SOPs must exist to ensure that storage conditions in the patient-care setting are suitable for the CSP-specific storage requirements. Procedures include daily monitoring and documentation of drug storage refrigerators to ensure temperatures between 2° and 8° and the monthly inspection of all drug storage locations by compounding personnel. Inspections shall confirm compliance with appropriate storage conditions, separation of drugs and food, proper use of MDVs, and the avoidance of using single-dose products as MDVs. CSPs, as well as all other drug products, shall be stored in the patient-care area in such a way as to secure them from unauthorized personnel, visitors, and patients.

#### Readyng for Administration

Procedures essential for generally ensuring quality, especially sterility assurance, when readyng a CSP for its subsequent administration include proper hand washing, aseptic technique, site care, and change of administration sets. Additional procedures may also be essential for certain CSPs, devices, or techniques. Examples where such special procedures are needed include in-line filtration, the operation of automated infusion control devices, and the replenishment of CSPs into the reservoirs of implantable or portable infusion pumps. When CSPs are likely to be exposed to warmer than 30° for more than 1 hour during their administration to patients, the maintenance of their sterility and stability should be confirmed from either relevant and reliable sources or direct testing.

#### Redispsensed CSPs

The compounding facility shall have the sole authority to determine when unopened, returned CSPs may be redispsensed. Returned CSPs may be redispsensed only when personnel responsible for sterile compounding can ensure that such CSPs are sterile, pure, and stable (contain labeled strength of ingredients). The following may provide such assurance: the CSPs were maintained under continuous refrigeration and protected from light, if required, and no evidence of tampering or any readyng for use outside the compounding facility exists. Assignment of new storage times and BUDs that exceed the original dates for returned CSPs is permitted only when there is supporting evidence from sterility testing and quantitative assay of ingredients. Thus, initial preparation and thaw times should be documented and reliable measures should have been taken to prevent and detect tampering. Compliance with all procedures associated with maintaining product quality is essential. The CSPs shall not be redispsensed if there is not adequate assurance that preparation quality and packaging integrity (including the connections of devices, where applicable) were continuously maintained between the time the CSPs left and the time they were returned.

Additionally, CSPs shall not be redispsensed if redispsensing cannot be supported by the originally assigned BUD.

#### Education and Training

The assurance of CSPs' quality and packaging integrity is highly dependent on the proper adherence of all personnel to the pertinent SOPs. Compounding personnel shall design, implement, and maintain a formal education, training, and competency assessment program that encompasses all the functions and tasks addressed in the foregoing sections and all personnel to whom such functions and tasks are assigned. This program includes the assessment and documentation of procedural breaches, administration mishaps, side effects, allergic reactions, and complications associated with dosage or administration, such as extravasation. This program should be coordinated with the institution's adverse-events and incident reporting programs.

#### Packing and Transporting CSPs

The following sections describe how to maintain sterility and stability of CSPs until they are delivered to patient care locations for administration.

##### packing cpps for transit

When CSPs are distributed to locations outside the premises in which they are compounded, compounding personnel select packing containers and materials that are expected to maintain physical integrity, sterility, and stability of CSPs during transit. Packing is selected that simultaneously protects CSPs from damage, leakage, contamination, and degradation, and protects personnel who transport packed CSPs from harm. The SOP manual of the compounding facility specifically describes appropriate packing containers and insulating and stuffing materials, based on information from product specifications, vendors, and experience of compounding personnel. Written instructions that clearly explain how to safely open containers of packed CSPs are provided to patients and other recipients.

##### transit of cpps

Compounding facilities that ship CSPs to locations outside their own premises shall select modes of transport that are expected to deliver properly packed CSPs in undamaged, sterile, and stable condition to recipients.

Compounding personnel should ascertain that temperatures of CSPs during transit by the selected mode will not exceed the warmest temperature specified on the storage temperature range on CSP labels. It is recommended that compounding personnel communicate directly with the couriers to learn shipping durations and exposure conditions that CSPs may encounter.

Compounding personnel shall include specific handling and exposure instructions on the exteriors of containers packed with CSPs to be transported and obtain reasonable assurance of compliance therewith from transporters. Compounding personnel shall periodically review the delivery performance of couriers to ascertain that CSPs are being efficiently and properly transported.

#### Storage in Locations Outside Compounding Facilities

Compounding facilities that ship CSPs to patients and other recipients outside their own premises shall ascertain or provide, whichever is appropriate, the following assurances:

1. Labels and accessory labeling for CSPs include clearly readable BUDs, storage instructions, and disposal instructions for out-of-date units.
2. Each patient or other recipient is able to store the CSPs properly, including the use of a properly functioning refrigerator and freezer if CSPs are labeled for such storage.

#### PATIENT OR CAREGIVER TRAINING

A formal training program is provided as a means to ensure understanding and compliance with the many special and complex responsibilities placed on the patient or caregiver for the storage, handling, and administration of CSPs. The instructional objectives for the training program include all home care responsibilities expected of the patient or caregiver and is specified in terms of patient or caregiver competencies.

Upon the conclusion of the training program, the patient or caregiver should, correctly and consistently, be able to do the following:

1. Describe the therapy involved, including the disease or condition for which the CSPs are prescribed, goals of therapy, expected therapeutic outcome, and potential side effects of the CSPs.
2. Inspect all drug products, CSPs, devices, equipment, and supplies on receipt to ensure that proper temperatures were maintained during transport and that goods received show no evidence of deterioration or defects.
3. Handle, store, and monitor all drug products, CSPs, and related supplies and equipment in the home, including all special requirements related to same.
4. Visually inspect all drug products, CSPs, devices, and other items the patient or caregiver is required to use immediately prior to administration in a manner to ensure that all items are acceptable for use. For example, CSPs must be free from leakage, container cracks, particulates, precipitate, haziness, discoloration, or other deviations from the normal expected appearance, and the immediate packages of sterile devices must be completely sealed, with no evidence of loss of package integrity.
5. Check labels immediately prior to administration to ensure the right drug, dose, patient, and time of administration.
6. Clean the in-home preparation area, scrub hands, use proper aseptic technique, and manipulate all containers, equipment, apparatus, devices, and supplies used in conjunction with administration.
7. Employ all techniques and precautions associated with CSP administration; for example, preparing supplies and equipment, handling of devices, priming the tubing, and discontinuing an infusion.

8. Care for catheters, change dressings, and maintain site patency as indicated.
9. Monitor for and detect occurrences of therapeutic complications such as infection, phlebitis, electrolyte imbalance, and catheter misplacement.
10. Respond immediately to emergency or critical situations such as catheter breakage or displacement, tubing disconnection, clot formation, flow blockage, and equipment malfunction.
11. Know when to seek and how to obtain professional emergency services or professional advice.
12. Handle, contain, and dispose of wastes, such as needles, syringes, devices, biohazardous spills or residuals, and infectious substances.

Training programs include a hands-on demonstration and practice with actual items that the patient or caregiver is expected to use, such as CSP containers, devices, and equipment. The patient or caregiver practices aseptic and injection technique under the direct observation of a health professional.

The compounding facility, in conjunction with nursing or medical personnel, is responsible for ensuring initially and on an ongoing basis that the patient or caregiver understands, has mastered, and is capable of and willing to comply with all of these home care responsibilities. This is achieved through a formal, written assessment program. All specified competencies in the patient or caregiver training program are formally assessed. The patient or caregiver is expected to demonstrate to appropriate healthcare personnel mastery of assigned activities before being allowed to administer CSPs unsupervised by a health professional.

Printed material such as checklists or instructions provided during training may serve as continuing post-training reinforcement of learning or as reminders of specific patient or caregiver responsibilities. Post-training verbal counseling can also be used periodically, as appropriate, to reinforce training and to ensure continuing correct and complete fulfillment of responsibilities.

#### PATIENT MONITORING AND ADVERSE EVENTS REPORTING

Compounding facilities shall clinically monitor patients treated with CSPs according to the regulations and guidelines of their respective state healthcare practitioner licensure boards or of accepted standards of practice. Compounding facilities shall provide patients and other recipients of CSPs with a way to address their questions and report any concerns that they may have with CSPs and their administration devices.

The SOP manuals of compounding facilities shall describe specific instructions for receiving, acknowledging, and dating receipts, and for recording, or filing, and evaluating reports of adverse events and of the quality of preparation claimed to be associated with CSPs. Reports of adverse events with CSPs shall be reviewed promptly and thoroughly by compounding supervisors to correct and prevent future occurrences. Compounding personnel are encouraged to participate in adverse event reporting and product defects programs of the FDA and USP.

#### QUALITY ASSURANCE (QA) PROGRAM

A provider of CSPs shall have in place a formal QA program intended to provide a mechanism for monitoring, evaluating, correcting, and improving the activities and processes described in this chapter. Emphasis in the QA program is placed on maintaining and improving the quality of systems and the provision of patient care. In addition, the QA program ensures that any plan aimed at correcting identified problems also includes appropriate follow-up to make certain that effective corrective actions were performed.<sup>13</sup>

Characteristics of a QA program include the following:

1. Formalization in writing;
2. Consideration of all aspects of the preparations and dispensing of products as described in this chapter, including environmental testing and verification results;
3. Description of specific monitoring and evaluation activities;
4. Specification of how results are to be reported and evaluated;
5. Identification of appropriate follow-up mechanisms when action limits or thresholds are exceeded; and
6. Delineation of the individuals responsible for each aspect of the QA program.

In developing a specific plan, focus is on establishing objective, measurable indicators for monitoring activities and processes that are deemed high risk, high volume, or problem prone. In general, the selection of indicators and the effectiveness of the overall QA program is reassessed on an annual basis.

#### ABBREVIATIONS AND ACRONYMS

ACD	automated compounding device
ACPH	air changes per hour
ALARA	as low as reasonably achievable
ASHRAE	American Society of Heating, Refrigerating and Air-Conditioning Engineers
BI	biological indicator
BSC	biological safety cabinet
BUD	beyond-use date
CACI	compounding aseptic containment isolator
CAI	compounding aseptic isolator
CDC	Centers for Disease Control and Prevention
CETA	Controlled Environment Testing Association
cfu	colony-forming unit(s)
CSP	compounded sterile preparation
CSTD	closed-system vial-transfer device
DCA	direct compounding area
ECV	endotoxin challenge vial
EU	Endotoxin Unit
FDA	Food and Drug Administration
HEPA	high efficiency particulate air
HICPAC	Healthcare Infection Control Practices Advisory Committee
HVAC	heating, ventilation, and air conditioning
IPA	isopropyl alcohol
ISO	International Organization for Standardization
LAFW	laminar airflow workbench
MDVs	multiple-dose vials
MMWR	Morbidity and Mortality Weekly Report
NIOSH	National Institute for Occupational Safety and Health
NIST	National Institute of Standards and Technology

PEC	primary engineering control
PET	positron emission tomography
PPE	personnel protective equipment
psi	pounds per square inch
QA	quality assurance
SOP	standard operating procedure
SVI	sterile vial for injection
TSA	trypticase soy agar
USP	United States Pharmacopeia

## APPENDICES

## Appendix I. Principal Competencies, Conditions, Practices, and Quality Assurances That Are Required († "shall") and Recommended (‡ "should") in USP Chapter 797

note—This tabular appendix selectively abstracts and condenses the full text of 797 for rapid reference only. Compounding personnel are responsible for reading, understanding and complying with the full text and all official USP terminology, content, and conditions therein.

## INTRODUCTION

‡ Chapter purpose is to prevent harm and death to patients treated with CSPs.

† Chapter pertains to preparation, storage, and transportation, but not administration, of CSPs.

† Personnel and facilities to which 797 applies; therefore, for whom and which it may be enforced by regulatory and accreditation authorities.

† Types of preparations designated to be CSPs according to their physical forms, and their sites and routes of administration to patients.

† Compounding personnel must be meticulously conscientious to preclude contact contamination of CSPs both within and outside ISO Class 5 areas.

## ORGANIZATION

† All compounding personnel shall be responsible for understanding fundamental practices and precautions within USP 797, for developing and implementing appropriate procedures, and for continually evaluating these procedures and the quality of final CSPs to prevent harm.

## DEFINITIONS

† Twenty-eight terms are defined and integral to complying with USP 797.

## RESPONSIBILITY OF COMPOUNDING PERSONNEL

† Practices and quality assurances required to prepare, store, and transport CSPs that are sterile, and acceptably accurate, pure, and stable.

## CSP MICROBIAL CONTAMINATION RISK LEVELS

† Proper training and evaluation of personnel, proper cleansing and garbing of personnel, proper cleaning and disinfecting of compounding work environments, and proper maintenance and monitoring of controlled environmental locations (all of which are detailed in their respective sections).

## Low-Risk Level CSPs

† Aseptic manipulations within an ISO Class 5 environment using three or fewer sterile products and entries into any container.

† In absence of passing sterility test, store not more than 48 hours at controlled room temperature, 14 days at cold temperature, and 45 days in solid frozen state at  $-25^{\circ}$  to  $-10^{\circ}$  or colder.

† Media-fill test at least annually by compounding personnel.

## Low-Risk Level CSPs with 12-Hour or Less BUD

† Fully comply with all four specific criteria.

‡ Sinks should not be located adjacent to the ISO Class 5 primary engineering control.

‡ Sinks should be separated from the immediate area of the ISO Class 5 primary engineering control device.

## Medium-Risk Level CSPs

† Aseptic manipulations within an ISO Class 5 environment using prolonged and complex mixing and transfer, more than three sterile products and entries into any container, and pooling ingredients from multiple sterile products to prepare multiple CSPs.

† In absence of passing sterility test, store not more than 30 hours at controlled room temperature, 9 days at cold temperature, and 45 days in solid frozen state at  $-25^{\circ}$  to  $-10^{\circ}$  or colder.

† Media-fill test at least annually by compounding personnel.

## High-Risk Level CSPs

† Confirmed presence of nonsterile ingredients and devices, or confirmed or suspected exposure of sterile ingredients for more than one hour to air quality inferior to ISO Class 5 before final sterilization.

† Sterilization method verified to achieve sterility for the quantity and type of containers.

† Meet allowable limits for bacterial endotoxins.

† Maintain acceptable strength and purity of ingredients and integrity of containers after sterilization.

† In absence of passing sterility test, store not more than 24 hours at controlled room temperature, 3 days at cold temperature, and 45 days in solid frozen state at  $-25^{\circ}$  to  $-10^{\circ}$  or colder.

† Media-fill test at least semiannually by compounding personnel.

## PERSONNEL TRAINING AND EVALUATION IN ASEPTIC MANIPULATIONS SKILLS

† Pass didactic, practical skill assessment and media-fill testing initially, followed by an annual assessment for a low- and medium-risk level compounding and semi-annual assessment for high-risk level compounding.

† Compounding personnel who fail written tests, or whose media-fill test vials result in gross microbial colonization, shall be immediately restructured and re-evaluated by expert compounding personnel to ensure correction of all aseptic practice deficiencies.

## IMMEDIATE-USE CSPs

† Fully comply with all six specified criteria.

## SINGLE-DOSE AND MULTIPLE-DOSE CONTAINERS

† Beyond-use date 28 days, unless specified otherwise by the manufacturer, for closure sealed multiple-dose containers after initial opening or entry.

† Beyond-use time of 6 hours, unless specified otherwise by the manufacturer, for closure sealed single-dose containers in ISO Class 5 or cleaner air after initial opening or entry.

Beyond-use time of 1 hour for closure sealed single-dose containers after being opened or entered in worse than ISO Class 5 air.

† Storage of opened single-dose ampuls is not permitted.

#### HAZARDOUS DRUGS AS CSPs

† Appropriate personnel protective equipment.

† Appropriate primary engineering controls (BSCs and CACIs) are used for concurrent personnel protection and exposure of critical sites.

† Hazardous drugs shall be stored separately from other inventory in a manner to prevent contamination and personnel exposure.

† At least 0.01 inch water column negative pressure and 12 air changes per hour in non-cleanrooms in which CACIs are located.

† Hazardous drugs shall be handled with caution at all times using appropriate chemotherapy gloves during receiving, distribution, stocking, inventorying, preparing for administration, and disposal.

† Hazardous drugs shall be prepared in an ISO Class 5 environment with protective engineering controls in place, and following aseptic practices specified for the appropriate contamination risk levels.

† Access to drug preparation areas shall be limited to authorized personnel.

† A pressure indicator shall be installed that can readily monitor room pressurization, which is documented daily.

† Annual documentation of full training of personnel regarding storage, handling, and disposal of hazardous drugs.

† When used, a CSTD shall be used in an ISO Class 5 primary engineering control device.

† At least 0.01 inch water column negative pressure is required for compounding of hazardous drugs.

‡ Negative-pressure buffer area is not required for low-volume compounding operations when CSTD is used in BSC or CACI.

† Compounding personnel of reproductive capability shall confirm in writing that they understand the risks of handling hazardous drugs.

† Disposal of all hazardous drug wastes shall comply with all applicable federal and state regulations.

‡ Total external exhaust of primary engineering controls.

‡ Assay of surface wipe samples every 6 months.

#### RADIOPHARMACEUTICALS AS CSPs

† Positron Emission Tomography is according to USP chapter 823.

† Appropriate primary engineering controls and radioactivity containment and shielding.

† Radiopharmaceuticals compounded from sterile components, in closed sterile containers, with volume of 100 mL or less for a single-dose injection or not more than 30 mL taken from a multiple-dose container shall be designated as and conform to the standards for low-risk level CSPs.

† Radiopharmaceutical vials, designed for multi-use, compounded with technetium-99m, exposed to ISO Class 5 environment and punctured by needles with no direct contact contamination may be used up to the time indicated by manufacturers' recommendations.

† Location of primary engineering controls permitted in ISO Class 8 controlled environment.

† Technetium-99m/Molybdenum-99 generators used according to manufacturer, state, and federal requirements.

† Radiopharmaceuticals prepared as low-risk level CSPs with 12-hour or less BUD shall be prepared in a segregated compounding area.

† Materials and garb exposed in patient-care and treatment area shall not cross a line of demarcation into the segregated compounding area.

† Technetium-99m/Molybdenum-99 generators must be eluted in ISO Class 8 conditions.

† Segregated compounding area will be designated with a line of demarcation.

‡ Storage and transport of properly shielded vials of radiopharmaceutical CSPs may occur in a limited access ambient environment without a specific ISO class designation.

#### ALLERGEN EXTRACTS AS CSPs

† Allergen extracts as CSPs are not subject to the personnel, environmental, and storage requirements for all CSP Microbial Contamination Risk Levels when certain criteria are met.

#### VERIFICATION OF COMPOUNDING ACCURACY AND STERILITY

† Review labels and document correct measurements, aseptic manipulations, and sterilization procedures to confirm correct identity, purity, and strength of ingredients in, and sterility of, CSPs.

‡ Assay finished CSPs to confirm correct identity and, or, strength of ingredients.

‡ Sterility test finished CSPs.

#### Sterilization Methods

† Verify that methods achieve sterility while maintaining appropriate strength, purity, quality, and packaging integrity.

‡ Prove effectiveness by USP chapter 71, equivalent, or superior sterility testing.

#### Sterilization of High-Risk Level CSPs by Filtration

† Nominal 0.2-µm pore size sterile membranes that are chemically and physically compatible with the CSP.

† Complete rapidly without filter replacement.

† Subject filter to manufacturer's recommended integrity test (e.g., bubble point test) after filtering CSPs.

#### Sterilization of High-Risk Level CSPs by Steam

† Test to verify the mass of containers to be sterilized will be sterile after the selected exposure duration in the particular autoclave.

† Ensure live steam contacts all ingredients and surfaces to be sterilized.

† Pass solutions through a 1.2-µm or smaller nominal pore size filter into final containers to remove particulates before sterilization.

† Heated filtered air shall be evenly distributed throughout the chamber by a blower device.

† Dry heat shall only be used for those materials that cannot be sterilized by steam, when the moisture would either damage or be impermeable to the materials.

† Sufficient space shall be left between materials to allow for good circulation of the hot air.

† The description of dry heat sterilization conditions and duration for specific CSPs shall be included in written documentation in the compounding facility. The effectiveness of dry heat sterilization shall be verified using appropriate biological indicators and other confirmation.

‡ The oven should be equipped with a system for controlling temperature and exposure period.

#### Depyrogenation by Dry Heat

† Dry heat depyrogenation shall be used to render glassware or containers, such as vials free from pyrogens as well as viable microbes.

† The description of the dry heat depyrogenation cycle and duration for specific load items shall be included in written documentation in the compounding facility.

† The effectiveness of the dry heat depyrogenation cycle shall be verified using endotoxin challenge vials (ECVs).

The bacterial endotoxin test should be performed on the ECVs to verify the cycle is capable of achieving a 3 log reduction in endotoxin.

#### ENVIRONMENTAL QUALITY AND CONTROL

Exposure of Critical Sites

† ISO Class 5 or better air.

† Preclude direct contact (e.g., touch and secretions) contamination.

ISO Class 5 Air Sources, Buffer Areas, and Ante-Areas

† A buffer area is an area that provides at least ISO Class 7 air quality.

† New representations of facility layouts.

† Each compounding facility shall ensure that each source of ISO Class 5 environment for exposure of critical sites and sterilization by filtration is properly located, operated, maintained, monitored, and verified.

† Devices (e.g., computers and printers) and objects (e.g., carts and cabinets) can be placed in buffer areas and shall be verified by testing or monitoring.

Viable and Nonviable Environmental Sampling (ES) Testing

† Environmental sampling shall occur as part a comprehensive quality management program and shall occur minimally when several conditions exist.

‡ The ES program should provide information to staff and leadership to demonstrate that the engineering controls are maintaining an environment within the compounding area that consistently maintains acceptably low viable and nonviable particle levels.

Environmental Nonviable Particle Testing Program

† Certification and testing of primary (LAFWs, BSCs, CAIs and CACIs) and secondary engineering controls (buffer and ante areas) shall be performed by a qualified individual no less than every six months and whenever the device or room is relocated, altered, or major service to the facility is performed. Certification procedures such as those outlined in the CETA Certification Guide for Sterile Compounding Facilities (CAG-003-2006) shall be used.

Total Particle Counts

† Certification that each ISO classified area (e.g., ISO Class 5, 7 and 8) is within established guidelines shall be performed no less than every 6 months and whenever the LAFW, BSC, CAI, or CACI is relocated or the physical structure of the buffer room or ante-area has been altered.

† Testing shall be performed by qualified operators using current, state-of-the-art electronic equipment with results meeting ISO Class 5, 7, or 8 depending on the requirements of the area.

† All certification records shall be maintained and reviewed by supervising personnel or other designated employee to ensure that the controlled environments comply with the proper air cleanliness, room pressures, and air changes per hour.

Pressure Differential Monitoring

† A pressure gauge or velocity meter shall be installed to monitor the pressure differential or airflow between the buffer area and ante-area, and the ante-area and the general environment outside the compounding area.

† The results shall be reviewed and documented on a log at least every work shift (minimum frequency shall be at least daily) or by a continuous recording device.

† The pressure between the ISO Class 7 and general pharmacy area shall not be less than 5 Pa (0.02 inch water column (w.c.)).

† In facilities where low- and medium-risk level CSPs are prepared, differential airflow shall maintain a minimum velocity of 0.2 meter/second (40 fpm) between buffer area and ante-area.

Environmental Viable Airborne Particle Testing Program—Sampling Plan

† An appropriate environmental sampling plan shall be developed for airborne viable particles based on a risk assessment of compounding activities performed.

† Selected sampling sites shall include locations within each ISO Class 5 environment and in the ISO Class 7 and 8 areas, and the segregated compounding areas at greatest risk of contamination (e.g., work areas near the ISO Class 5 environment, counters near doors, pass-through boxes).

† The plan shall include sample location, method of collection, frequency of sampling, volume of air sampled, and time of day as related to activity in the compounding area and action levels.

‡ It is recommended that compounding personnel refer to USP Chapter [Microbiological Evaluation of Clean Rooms and Other Controlled Environments](#) 1116 and the CDC Guidelines for Environmental Infection Control in Healthcare Facilities-2003 for more information.

Growth Media

† A general microbiological growth medium such as Soybean-Casein Digest Medium (also known as trypticase soy broth (TSB) or agar (TSA)) shall be used to support the growth of bacteria.

† Malt extract agar (MEA) or some other media that supports the growth of fungi shall be used in high-risk level compounding environments.

† Media used for surface sampling shall be supplemented with additives to neutralize the effects of disinfecting agents (e.g., TSA with lecithin and polysorbate 80).

Viable Air Sampling

† Evaluation of airborne microorganisms using volumetric collection methods in the controlled air environments shall be performed by properly trained individuals for all compounding risk levels.

† Impaction shall be the preferred method of volumetric air sampling.

† For low-, medium-, and high-risk level compounding, air sampling shall be performed at locations that are prone to contamination during compounding activities and during other activities like staging, labeling, gowning, and cleaning.

† Locations shall include zones of air backwash turbulence within laminar airflow workbench and other areas where air backwash turbulence may enter the compounding area.

† For low-risk level CSPs with 12-hour or less BUD, air sampling shall be performed at locations inside the ISO Class 5 environment and other areas that are in close proximity to the ISO class 5 environment, during the certification of the primary engineering control.

‡ Consideration should be given to the overall effect the chosen sampling method will have on the unidirectional airflow within a compounding environment.

Air Sampling Devices

† The instructions in the manufacturer's user manual for verification and use of electric air samplers that actively collect volumes of air for evaluation shall be followed.

† A sufficient volume of air (400–1000 liters) shall be tested at each location in order to maximize sensitivity.

‡ It is recommended that compounding personnel also refer to USP Chapter 1116, which can provide more information on the use of volumetric air samplers and volume of air that should be sampled to detect environmental bioburden excursions.

Air Sampling Frequency and Process

† Air sampling shall be performed at least semiannually (i.e. every 6 months), as part of the re-certification of facilities and equipment for area where primary engineering controls are located.

† A sufficient volume of air shall be sampled and the manufacturer's guidelines for use of the electronic air sampling equipment followed.

‡ Any facility construction or equipment servicing may require the need to perform air sampling during these events.

## Incubation Period

† The microbial growth media plates used to collect environmental sampling are recovered, covers secured (e.g., taped), inverted, and incubated at a temperature and for a time period conducive to multiplication of microorganisms.

† The number of discrete colonies of microorganisms shall be counted and reported as colony-forming units (cfu) and documented on an environmental monitoring form. Counts from air monitoring need to be transformed into cfu/cubic meter of air and evaluated for adverse trends.

‡ TSA should be incubated at  $35^{\circ}\pm 2^{\circ}$  for 2–3 days.

‡ MEA or other suitable fungal media should be incubated at  $28^{\circ}\pm 2^{\circ}$  for 5–7 days.

## Action Levels, Documentation and Data Evaluation

† Sampling data shall be collected and reviewed on a periodic basis as a means of evaluating the overall control of the compounding environment.

† Competent microbiology personnel shall be consulted if an environmental sampling consistently shows elevated levels of microbial growth.

† An investigation into the source of the environmental contamination shall be conducted.

‡ Any cfu count that exceeds its respective action level should prompt a re-evaluation of the adequacy of personnel work practices, cleaning procedures, operational procedures, and air filtration efficiency within the aseptic compounding location.

‡ Table titled, Recommended Action Levels for Microbial Contamination should only be used as a guideline

## Facility Design and Environmental Controls

† Compounding facilities are physically designed and environmentally controlled to minimize airborne contamination from contacting critical sites.

† Compounding facilities shall provide a comfortable and well-lighted working environment, which typically includes a temperature of  $20^{\circ}$  or cooler to maintain comfortable conditions for compounding personnel when attired in the required aseptic compounding garb.

† Primary engineering controls provide unidirectional (i.e., laminar) HEPA air at a velocity sufficient to prevent airborne particles from contacting critical sites.

† In situ air pattern analysis via smoke studies shall be conducted at the critical area to demonstrate unidirectional airflow and sweeping action over and away from the product under dynamic conditions.

† Policies and procedures for maintaining and working within the primary engineering control area shall be written and followed. The policies and procedures will be determined by the scope and risk levels of the aseptic compounding activities used during the preparation of the CSPs.

† The principles of HEPA-filtered unidirectional airflow in the work environment shall be understood and practiced in the compounding process in order to achieve the desired environmental conditions.

† Clean rooms for nonhazardous and nonradioactive CSPs are supplied with HEPA that enters from ceilings with return vents low on walls, and that provides not less than 30 air changes per hour.

† Buffer areas maintain 0.02- to 0.05-inch water column positive pressure, and do not contain sinks or drains.

† Air velocity from buffer rooms or zones to ante-areas is at least 40 feet/minute.

† The primary engineering controls shall be placed within a buffer area in such a manner as to avoid conditions that could adversely affect their operation.

† The primary engineering controls shall be placed out of the traffic flow and in a manner to avoid disruption from the HVAC system and room cross-drafts.

† HEPA-filtered supply air shall be introduced at the ceiling.

† All HEPA filters shall be efficiency tested using the most penetrating particle size and shall be leak tested at the factory and then leak tested again in situ after installation.

† Activities and tasks carried out within the buffer area shall be limited to only those necessary when working within a controlled environment.

† Only the furniture, equipment, supplies, and other material required for the compounding activities to be performed shall be brought into the room.

† Surfaces and essential furniture in buffer rooms or zones and clean rooms shall be nonporous, smooth, nonshedding, impermeable, cleanable, and resistant to disinfectants.

† The surfaces of ceilings, walls, floors, fixtures, shelving, counters, and cabinets in the buffer area shall be smooth, impervious, free from cracks and crevices, and nonshedding, thereby promoting cleanability, and minimizing spaces in which microorganisms and other contaminants may accumulate.

† The surfaces shall be resistant to damage by disinfectant agents.

† Junctures of ceilings to walls shall be coved or caulked to avoid cracks and crevices where dirt can accumulate.

† Ceiling tiles shall be caulked around each perimeter to seal them to the support frame.

† The exterior lens surface of ceiling lighting fixtures shall be smooth, mounted flush, and sealed.

† Any other penetrations through the ceiling or walls shall be sealed.

† The buffer area shall not contain sources of water (sinks) or floor drains. Work surfaces shall be constructed of smooth, impervious materials, such as stainless steel or molded plastic, so that they are easily cleaned and disinfected.

† Carts shall be of stainless steel wire, nonporous plastic, or sheet metal construction with good quality, cleanable casters to promote mobility.

† Storage shelving, counters, and cabinets shall be smooth, impervious, free from cracks and crevices, nonshedding, cleanable, and disinfectable.

† Their number, design, and manner of installation the items above shall promote effective cleaning and disinfection.

‡ If ceilings consist of inlaid panels, the panels should be impregnated with a polymer to render them impervious and hydrophobic.

‡ Dust-collecting overhangs, such as ceiling utility pipes, or ledges, such as windowsills, should be avoided.

‡ Air returns should be mounted low on the wall creating a general top-down dilution of room air with HEPA-filtered make-up air.

## Placement of Primary Engineering Controls Within ISO Class 7 Buffer Areas

† Primary engineering controls for nonhazardous and nonradioactive CSPs are located in buffer areas, except for CAIs that are proven to maintain ISO Class 5 air when particle counts are sampled 6 to 12 inches upstream of critical site exposure areas during performance of normal inward and outward transfer of materials, and compounding manipulations when such CAIs are located in air quality worse than ISO Class 7.

† Presterilization procedures for high-risk level CSPs, such as weighing and mixing, shall be completed in no worse than an ISO Class 8 environment.

† Primary engineering controls shall be located out of traffic patterns and away from room air currents that could disrupt the intended airflow patterns.

† When isolators are used for sterile compounding, the recovery time to achieve ISO Class 5 air quality shall be documented and internal procedures developed to ensure that adequate recovery time is allowed after material transfer before and during compounding operations.

† When compounding activities require the manipulation of a patient's blood-derived or other biological material (e.g., radiolabeling a patient's or a donor's white blood cells), the manipulations shall be clearly separated from routine material-handling procedures and equipment used in CSP preparation activities, and they shall be controlled by specific standard operating procedures in order to avoid any cross-contamination.

† Food, drinks, and items exposed in patient care areas, and unpacking of bulk supplies and personnel cleansing and garbing are prohibited from buffer areas or rooms.

† Demarcation designation between buffer areas or rooms and ante-areas.

† Antiseptic hand cleansing and sterile gloves in buffer areas or rooms.

‡ Packaged compounding supplies and components, such as needles, syringes, tubing sets, and small- and large-volume parenterals, should be uncartoned and wiped down with a

disinfectant that does not leave a residue (e.g., sterile 70% IPA) when possible in an ante-area, of ISO Class 8 air quality, before being passed into the buffer areas.

#### Cleaning and Disinfecting the Sterile Compounding Areas

† Trained personnel write detailed procedures including cleansers, disinfectants, and non-shedding wipe and mop materials.

† Cleaning and disinfecting surfaces in the LAFWs, BSCs, CAIs, and CACIs shall be cleaned and disinfected frequently, including at the beginning of each work shift, before each batch preparation is started, every 30 minutes during continuous compounding periods of individual CSPs, when there are spills, and when surface contamination is known or suspected from procedural breaches.

† Trained compounding personnel are responsible for developing, implementing, and practicing the procedures for cleaning and disinfecting the DCAs written in the SOPs.

† Cleaning and disinfecting shall occur before compounding is performed. Items shall be removed from all areas to be cleaned, and surfaces shall be cleaned by removing loose material and residue from spills, e.g., water-soluble solid residues are removed with Sterile Water (for Injection or Irrigation) and low-shedding wipes. This shall be followed by wiping with a residue-free disinfecting agent, such as sterile 70% IPA, which is allowed to dry before compounding begins.

† Work surfaces in ISO Class 7 and 8 areas and segregated compounding areas are cleaned at least daily.

† Dust and debris shall be removed when necessary from storage sites for compounding ingredients and supplies, using a method that does not degrade the ISO Class 7 or 8 air quality.

† Floors in ISO Class 7 and 8 areas are cleaned daily when no compounding occurs.

† IPA (70% isopropyl alcohol) remains on surfaces to be disinfected for at least 30 seconds before such surfaces are used to prepare CSPs.

† Emptied shelving, walls, and ceilings in ante-areas are cleaned and disinfected at least monthly.

† Mopping shall be performed by trained personnel using approved agents and procedures described in the written SOPs.

† Cleaning and disinfecting agents, their schedules of use and methods of application shall be in accordance with written SOPs and followed by custodial and/or compounding personnel.

† All cleaning materials, such as wipers, sponges, and mops, shall be nonshedding, preferably composed of synthetic micro fibers, and dedicated to use in the buffer area, or ante-area, and segregated compounding areas and shall not be removed from these areas except for disposal.

† If cleaning materials are reused (e.g., mops), procedures shall be developed (based on manufacturer recommendations) that ensure that the effectiveness of the cleaning device is maintained and repeated use does not add to the bioburden of the area being cleaned.

† Supplies and equipment removed from shipping cartons shall be wiped with a suitable disinfecting agent (e.g., sterile 70% IPA) delivered from a spray bottle or other suitable delivery method.

† After the disinfectant is sprayed or wiped on a surface to be disinfected, the disinfectant shall be allowed to dry, and during this time the item shall not be used for compounding purposes.

† Sterile 70% IPA wetted gauze pads or other particle-generating material shall not be used to disinfect the sterile entry points of packages and devices.

#### Personnel Cleansing and Garbing

† Personnel shall also be thoroughly competent and highly motivated to perform flawless aseptic manipulations with ingredients, devices, and components of CSPs.

† Personnel with rashes, sunburn, weeping sores, conjunctivitis, active respiratory infection, and cosmetics are prohibited from preparing CSPs.

† Compounding personnel shall remove personal outer garments; cosmetics; artificial nails; hand, wrist, and body jewelry that can interfere with the fit of gowns and gloves; and visible body piercing above the neck.

† Order of compounding garb and cleansing in ante-area: shoes or shoe covers, head and facial hair covers, face mask, fingernail cleansing, hand and forearm washing and drying; non-shedding gown.

† Order of cleansing and gloving in buffer room or area: hand cleansing with a persistently active alcohol-based product with persistent activity; allow hands to dry; don sterile gloves.

† Routinely disinfect gloves with sterile 70% IPA after contacting nonsterile objects.

† Inspect gloves for holes and replace when breaches are detected.

† Personnel repeat proper procedures after they are exposed to direct contact contamination or worse than ISO Class 8 air.

† These requirements are exempted only for immediate-use CSPs and CAIs for which manufacturers provide written documentation based on validated testing that such personnel practices are not required to maintain sterility in CSPs.

#### Personnel Training and Competency Evaluation of Garbing, Aseptic Work Practices and Cleaning/Disinfection Procedures

† Personnel who prepare CSPs shall be trained conscientiously and skillfully by expert personnel, multi-media instructional sources, and professional publications in the theoretical principles and practical skills of garbing procedures, aseptic work practices, achieving and maintaining ISO Class 5 environmental conditions, and cleaning and disinfection procedures.

† This training shall be completed and documented before any compounding personnel begin to prepare CSPs.

† Compounding personnel shall complete didactic training, pass written competence assessments, undergo skill assessment using observational audit tools, and media-fill testing.

† Media-fill testing of aseptic work skills shall be performed initially before beginning to prepare CSPs and at least annually thereafter for low- and medium-risk level compounding; and semiannually for high-risk level compounding.

† Compounding personnel who fail written tests, observational audits, or whose media-fill test vials have one or more units showing visible microbial contamination, shall be retrained and re-evaluated by expert compounding personnel to ensure correction of all aseptic work practice deficiencies.

† Compounding personnel shall pass all evaluations prior to resuming compounding of sterile preparations.

† Compounding personnel must demonstrate proficiency of proper hand hygiene, garbing, and consistent cleaning procedures in addition to didactic evaluation and aseptic media fill.

† Cleaning and disinfecting procedures performed by other support personnel shall be thoroughly trained in proper hand hygiene, and garbing, cleaning, and disinfection procedures by a qualified aseptic compounding expert.

† Support personnel shall routinely undergo performance evaluation of proper hand hygiene, garbing, and all applicable cleaning and disinfecting procedures conducted by a qualified aseptic compounding expert.

#### Competency Evaluation of Garbing and Aseptic Work Practices

† Compounding personnel shall be evaluated initially prior to beginning compounding CSPs and whenever an aseptic media fill is performed using a Sample Form for Assessing Hand Hygiene and Garbing Related Practices of Compounding Personnel and the personnel glove fingertip sampling procedures.

#### Aseptic Work Practice Assessment and Evaluation via Personnel Glove Fingertip Sampling

† Monitoring of compounding personnel glove fingertips shall be performed for all CSP risk level compounding.

† Glove fingertip sampling shall be used to evaluate the competency of personnel in performing hand hygiene and garbing procedures in addition to educating compounding personnel on proper work practices.

† All personnel shall demonstrate competency in proper hand hygiene and garbing procedures in addition to aseptic work practices.

† Sterile contact agar plates shall be used to sample the gloved fingertips of compounding personnel after garbing to assess garbing competency and after completing the media-fill preparation.

Gloves shall not be disinfected with sterile 70% IPA immediately prior to sampling.

#### Garbing and Gloving Competency Evaluation

† Compounding personnel shall be visually observed during the process of performing hand hygiene and garbing procedures.

† The visual observation shall be documented on a Sample Form for Assessing Hand Hygiene and Garbing Related Practices of Compounding Personnel and maintained to provide a permanent record of and long-term assessment of personnel competency.

#### Gloved Fingertip Sampling

† Immediately after the compounding personnel completes the hand hygiene and garbing procedure, the evaluator shall collect a gloved fingertip and thumb sample from both hands of the compounding personnel onto appropriate agar plates by lightly pressing each finger tip into the agar.

† The plates shall be incubated for the appropriate incubation period and at the appropriate temperature.

† All employees shall successfully complete an initial competency evaluation and gloved fingertip/thumb sampling procedure (0 cfu) no less than three times before initially being allowed to compound CSPs for human use.

† After completing the initial gowning and gloving competency evaluation, re-evaluation of all compounding personnel shall occur at least annually for low- and medium-risk level CSPs and semiannually for high-risk level CSPs before being allowed to continue compounding CSPs.

† Gloves shall not be disinfected with sterile 70% IPA prior to testing.

† The sampled gloves shall be immediately discarded and proper hand hygiene performed after sampling. The nutrient agar plates shall be incubated as stated below.

† The cfu action level for gloved hands shall be based on the total number of cfu on both gloves and not per hand.

‡ Results should be reported separately as number of cfu per employee per hand (left hand, right hand).

#### Incubation Period

† At the end of the designated sampling period, the agar plates are recovered, covers secured, inverted and incubated at a temperature and for a time period conducive to multiplication of microorganisms. Trypticase soy agar (TSA) with lecithin and polysorbate 80 shall be incubated at  $35^{\circ}\pm 2^{\circ}$  for 2–3 days.

#### Aseptic Manipulation Competency Evaluation

† All compounding personnel shall have their aseptic technique and related practice competency evaluated initially during the media-fill test procedure and subsequent annual or semiannual media-fill test procedures on the Sample Form for Assessing Aseptic Technique and Related Practices of Compounding Personnel.

#### Media-Fill Test Procedure

† The skill of personnel to aseptically prepare CSPs shall be evaluated using sterile fluid bacterial culture media-fill verification.

† Media-filled vials shall be incubated within a range of  $35^{\circ}\pm 2^{\circ}$  for 14 days.

#### Surface Cleaning and Disinfection Sampling and Assessment

† Surface sampling shall be performed in all ISO classified areas on a periodic basis and can be accomplished using contact plates and/or swabs and shall be done at the conclusion of compounding.

† Locations to be sampled shall be defined in a sample plan or on a form.

#### Cleaning and Disinfecting Competency Evaluation

† Compounding personnel and other personnel responsible for cleaning shall be visually observed during the process of performing cleaning and disinfecting procedures during initial personnel training on cleaning procedures, changes in cleaning staff and at the completion of any Media-Fill Test Procedure.

† Visual observation shall be documented on a Sample Form for Assessing Cleaning and Disinfection Procedures and maintained to provide a permanent record of, and long-term assessment of, personnel competency.

#### Surface Collection Methods

† Immediately after sampling a surface with the contact plate, the sampled area shall be thoroughly wiped with a non-shedding wipe soaked in sterile 70% IPA.

‡ Results should be reported as cfu per unit of surface area.

#### Action Levels, Documentation, and Data Evaluation

† Environmental sampling data shall be collected and reviewed on a routine basis as a means of evaluating the overall control of the compounding environment.

† If an activity consistently shows elevated levels of microbial growth, competent microbiology personnel shall be consulted.

† An investigation into the source of the contamination shall be conducted.

† When gloved fingertip sample results exceed action levels after proper incubation, a review of hand hygiene and garbing procedures as well as glove and surface disinfection procedures and work practices shall be performed and documented.

‡ Any cfu count that exceeds its respective action level should prompt a re-evaluation of the adequacy of personnel work practices, cleaning procedures, operational procedures, and air filtration efficiency within the aseptic compounding location.

#### SUGGESTED STANDARD OPERATING PROCEDURES

† All facilities are required to have these, and they must include at least the items enumerated in this section.

#### FINISHED PREPARATION RELEASE CHECKS AND TESTS

##### Inspection of Solution Dosage Forms and Review of Compounding Procedures

† Review procedures and documents to ensure sterility, purity, correct identities and amounts of ingredients, and stability.

† Visually inspect for abnormal particulate matter and color, and intact containers and seals.

##### Sterility Testing

† High-risk level CSPs prepared in batches of more than 25 identical containers, or exposed longer than 12 hours at  $2^{\circ}$  to  $8^{\circ}$ , and 6 hours at warmer than  $8^{\circ}$  before being sterilized.

##### Bacterial Endotoxin (Pyrogen) Testing

† High-risk level CSPs, excluding those for inhalation and ophthalmic administration, prepared in batches of more than 25 identical containers, or exposed longer than 12 hours at  $2^{\circ}$  to  $8^{\circ}$ , and 6 hours at warmer than  $8^{\circ}$ , before being sterilized.

##### Identity and Strength Verification of Ingredients

† Written procedures to verify correct identity, quality, amounts, and purities of ingredients used in CSPs.

† Written procedures to ensure labels of CSPs contain correct names and amounts or concentrations of ingredients, total volumes, beyond-use dates, storage conditions, and route(s) of administration.

#### STORAGE AND BEYOND-USE DATING

##### Determining Beyond-Use Dates

† Use the general criteria in USP 795 in the absence of direct stability-indicating assays or authoritative literature that supports longer durations.

## MAINTAINING STERILITY, PURITY, AND STABILITY OF DISPENSED AND DISTRIBUTED CSPs

† Written procedures for proper packaging, storage, and transportation conditions to maintain sterility, quality, purity, and strength of CSPs.

## Redispersed CSPs

† When sterility, and acceptable purity, strength, and quality can be ensured.

† Assignment of sterility storage times and stability beyond-use dates that occur later than those of originally dispensed CSPs must be based on results of sterility testing and quantitative assay of ingredients.

## Packaging and Transporting CSPs

† Packaging maintains physical integrity, sterility, stability, and purity of CSPs.

† Modes of transport that maintain appropriate temperatures and prevent damage to CSPs.

## PATIENT OR CAREGIVER TRAINING

† Multiple component formal training program to ensure patients and caregivers understand the proper storage, handling, use, and disposal of CSPs.

## PATIENT MONITORING AND ADVERSE EVENTS REPORTING

† Written standard procedures describe means for patients to ask questions and report concerns and adverse events with CSPs, and for compounding supervisors to correct and prevent future problems.

‡ Adverse events and defects with CSPs reported to FDA's MedWatch and USP's MEDMARX programs.

Appendix II. Common Disinfectants Used in Health Care for Inanimate Surfaces and Noncritical Devices, and Their Microbial Activity and Properties<sup>1</sup>

## Chemical Category of Disinfectant

		Isopropyl alcohol	Accelerated Hydrogen peroxide <sup>3</sup>	Quaternary Ammonium (e.g., dodecyl dimethyl ammonium chloride)	Phenolics	Chlorine (e.g., sodium hypochlorite)	Iodophors (e.g., povidone-iodine)
Concentration Used		60–95%	0.5%	0.4–1.6% aq	0.4–1.6% aq	100–5000 ppm	30–50 ppm
Microbial Inactivation	Bacteria	+	+	+	+	+	+
	Lipophilic viruses	+	+	+	+	+	+
	Hydrophilic viruses	±	+	±	±	+	±
	M.tuberculosis	+	+	±	+	+	±
	Mycotic agents (fungi)	+	+	+	+	+	±
	Bacterial Spores	—	—	—	—	+	—
Important Chemical & Physical Properties	Shelf life >1 week	+	+	+	+	+	+
	Corrosive or deleterious effects	±	—	—	—	±	±
	Non-evaporable residue	—	—	+	+	—	+
	Inactivated by organic matter	+	±	+	±	+	+
	Skin irritant	±	—	+	+	+	±
	Eye irritant	+	—	+	+	+	+
	Respiratory irritant	—	—	—	—	+	—
	Systemic toxicity	+	—	+	+	+	+

Key to abbreviation and symbols: aq = diluted with water; ppm = parts per million; + = yes; — = no; ± = variable results.

1 Modified from World Health Organization, Laboratory Bio Safety Manual 1983 and Rutala WA, "Antiseptics, disinfection and sterilization in the hospital and related institutions," Manual of Clinical Microbiology, American Society for Microbiology, Washington, DC, 1995, pages 227-245.

2 Inactivation of the most common microorganisms (i.e., bacteria) occurs with a contact time of ≤1 minute; inactivation of spores requires longer contact times (e.g., 5-10 minutes for 5,000 ppm chlorine solution against C. difficile spores). Reference: Perez J, Springthorpe VS, Sattar SA, "Activity of selected oxidizing microbicides against the spores of Clostridium difficile: Relevance to environmental control," American Journal of Infection Control, August 2005, pages 320-325.

3 Accelerated hydrogen peroxide is a new generation of hydrogen peroxide-based germicides in which the potency and performance of the active ingredient have been enhanced and accelerated through the use of appropriate acids and detergents.

## Appendix III. Sample Form for Assessing Hand Hygiene and Garbing Related Practices of Compounding Personnel

	Printed name and position/title of person assessed:
Name of facility or location:	
Hand Hygiene and Garbing Practices: The qualified evaluator will check each space for which the person being assessed has acceptably completed the described activity, prints N/A if the activity is not applicable to the assessment session or N/O if the activity was not observed.*	
Presents in a clean appropriate attire and manner.	
Wears no cosmetics or jewelry (watches, rings, earrings, etc. piercing jewelry included) upon entry into ante-areas.	
Brings no food or drinks into or stored in the ante-areas or buffer areas.	
Is aware of the line of demarcation separating clean and dirty sides and observes required activities.	
Dons shoe covers or designated clean-area shoes one at a time, placing the covered or designated shoe on clean side of the line of demarcation, as appropriate.	
Dons beard cover if necessary.	
Dons head cover assuring that all hair is covered.	
Dons face mask to cover bridge of nose down to include chin.	
Performs hand hygiene procedure by wetting hands and forearms and washing using soap and warm water for at least 30 seconds.	
Dries hands and forearms using lint-free towel or hand dryer.	
Selects the appropriate sized gown examining for any holes, tears, or other defects.	
Dons gown and ensures full closure.	

Disinfects hands again using a waterless alcohol-based surgical hand scrub with persistent activity and allows hands to dry thoroughly before donning sterile gloves.
Dons appropriate sized sterile gloves ensuring that there is a tight fit with no excess glove material at the fingertips.
Examines gloves ensuring that there are no defects, holes, or tears.
While engaging in sterile compounding activities, routinely disinfects gloves with sterile 70% IPA prior to work in the direct compounding area (DCA) and after touching items or surfaces that may contaminate gloves.
Removes PPE on the clean side of the ante-area.
Removes gloves and performs hand hygiene.
Removes gown and discards it, or hangs it on hook if it is to be reused within the same work day.
Removes and discards mask, head cover, and beard cover (if used).
Removes shoe covers or shoes one at a time, ensuring that uncovered foot is placed on the dirty side of the line of demarcation and performs hand hygiene again. (Removes and discards shoe covers every time the compounding area is exited).

\*The person assessed is immediately informed of all unacceptable activities (i.e., spaces lacking check marks, N/A, or N/O) and shown and informed of specific corrections.

Signature of Person Assessed	Printed Name	Date

Appendix IV. Sample Form for Assessing Aseptic Technique and Related Practices of Compounding Personnel

Printed name and position/title of person assessed:

**Aseptic Technique, Safety, and Quality Assurance Practices:** The qualified evaluator checks each space for which the person being assessed has acceptably completed the described activity, prints N/A if the activity is not applicable to the assessment session or N/O if the activity was not observed.\*

Completes the Hand Hygiene and Garbing Competency Assessment Form.
Performs proper hand hygiene, garbing, and gloving procedures according to SOPs.
Disinfects ISO Class 5 device surfaces with an appropriate agent.
Disinfects components/vials with an appropriate agent prior to placing into ISO Class 5 work area.
Introduces only essential materials in a proper arrangement in the ISO Class 5 work area.
Does not interrupt, impede, or divert flow of first-air to critical sites.
Ensures syringes, needles, and tubing remain in their individual packaging and are only opened in ISO Class 5 work area.
Performs manipulations only in the appropriate DCA of the ISO Class 5 device.
Does not expose critical sites to contact contamination or worse than ISO Class 5 air.
Disinfects stoppers, injection ports, and ampul necks by wiping with sterile 70% IPA and allows sufficient time to dry.
Affixes needles to syringes without contact contamination.
Punctures vial stoppers and spikes infusion ports without contact contamination.
Labels preparation(s) correctly.
Disinfects sterile gloves routinely by wiping with sterile 70% IPA during prolonged compounding manipulations.
Cleans, sets up, and calibrates automated compounding device (e.g., "TPN compounder") according to manufacturer's instructions.
Disposes of sharps and waste according to institutional policy or recognized guidelines.

\*The person assessed is immediately informed of all unacceptable activities (i.e., spaces lacking check marks, N/A, or N/O) and shown and informed of specific corrections.

The person assessed is immediately informed of an unacceptable activity (i.e., spousal/parenting behaviour, HIV, or STD) and informed of specific consequences.

## Appendix V. Sample Form for Assessing Cleaning and Disinfection Procedures

Printed name and position/title of person assessed:

Cleaning and Disinfection Practices: The qualified evaluator will check each space for which the person being assessed has acceptably completed the described activity, prints N/A if the activity is not applicable to the assessment session or N/O if the activity was not observed.\*

---

### Daily Tasks:

Daily Tasks:	<p>Prepares correct concentration of disinfectant solution according to manufacturer's instructions.</p> <p>Uses appropriately labeled container for the type of surface to be cleaned (floor, wall, production bins, etc.).</p> <p>Documents disinfectant solution preparation.</p> <p>Follows garbing procedures when performing any cleaning activities.</p> <p>At the beginning of each shift, cleans all ISO Class 5 devices prior to compounding in the following order: walls, IV bar, automated compounders, and work surface.</p> <p>Uses a lint free wipe soaked with sterile 70% IPA or other approved disinfectant solution and allows to dry completely.</p> <p>Removes all compounding components and cleans all ISO Class 5 areas as stated above at the end of each shift.</p> <p>Cleans all counters and easily cleanable work surfaces.</p> <p>Mops floors, using the mop labeled "floors", starting at the wall opposite the room entry door; mops floor surface in even strokes toward the operator. Moves carts as needed to clean entire floor surface. Use of a microfiber cleaning system is an acceptable alternative to mops.</p> <p>In the ante-area, cleans sink and all contact surfaces; cleans floor with a disinfectant solution or uses microfiber cleaning system.</p>
--------------	--

## Monthly Tasks:

Monthly Cleaning	Performs monthly cleaning on a designated day. Prepares a disinfectant solution as stated in daily tasks that is appropriate for the surfaces to be cleaned.
Ante-Area Cleaning	Cleans buffer area and ante-area ceiling, walls, and storage shelving with a disinfectant solution and a mop or uses a microfiber cleaning system.
ISO Class 5 Cleaning	Once ISO Class 5 area is clean, cleans compounding room ceiling, followed by walls and ending with the floor. Uses appropriate labeled mops or microfiber cleaning system.
Buffer Area Cleaning	Cleans all buffer area totes and storage shelves by removing contents and using a germicidal detergent soaked lint free wipe, cleans the inside surfaces of the tote and then the entire exterior surfaces of the tote. Allows totes to dry. Prior to replacing contents into tote, wipes tote with sterile 70% IPA to remove disinfectant residue. Uses new wipe as needed.
Storage Area Cleaning	

Cleans all buffer area carts by removing contents and using germicidal detergent soaked lint free wipe, cleans all carts starting with the top shelf and top of post, working down to wheels. Cleans the under side of shelves in a similar manner. Uses a new wipe for each cart. Allows to dry. Wipes carts with sterile 70% IPA wetted lint-free wipe to remove any disinfectant residue. Uses new wipe as needed.

Cleans buffer area chairs, the interior and exterior of trash bins, and storage bins using disinfectant solution soaked lint free wipe.

Documents all cleaning activities as to who performed such activities with date and time noted.

\*The person assessed is immediately informed of all unacceptable activities (i.e., spaces lacking check marks, N/A, or N/O) and shown and informed of specific corrections.

#### « 801 » POLAROGRAPHY

Polarography is an electrochemical method of analysis based on the measurement of the current flow resulting from the electrolysis of a solution at a polarizable microelectrode, as a function of an applied voltage. The polarogram (see [Figure 1](#)) obtained by this measurement provides qualitative and quantitative information on electro-reducible and electro-oxidizable substances. The normal concentration range for substances being analyzed is from 10–2 molar to 10–5 molar.

In direct current (dc) polarography, the microelectrode is a dropping mercury electrode (DME) consisting of small reproducible drops of mercury flowing from the orifice of a capillary tube connected to a mercury reservoir. A saturated calomel electrode (SCE) with a large surface area is the most commonly employed reference electrode. As the voltage applied to the cell increases, only a very small residual current flows until the substance under assay undergoes reduction or oxidation. Then the current increases, at first gradually, then almost linearly with voltage, and it gradually reaches a limiting value as is shown in [Figure 1](#).

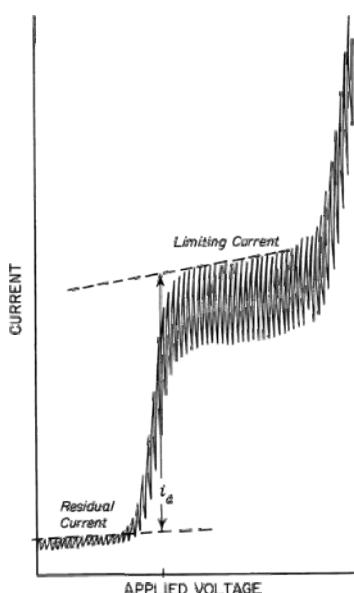

Fig. 1. Typical Polarogram Showing Change in Current Flow with Increasing Potential Applied to the Dropping Mercury Electrode.

On the initial rising portion of the polarographic wave, the increased flow of current results in a decrease in the concentration of the electro-active species at the electrode surface. As

voltage and current increase, the concentration of the reactive species decreases further to a minimal value at the electrode surface. The current is then limited by the rate at which the reacting species can diffuse from the bulk of the solution to the surface of the microelectrode. The final current rise is caused by the reaction of the supporting electrolyte. This large concentration of electrolyte is inert within the potential range used in the analysis, and it prevents the reactive species from reaching the electrode by electrical migration, thus assuring that the limiting current is diffusion-controlled.

Since, in the case of the DME, the electrode surface is being constantly renewed in a cyclic fashion, the current increases from a small value as the drop begins to form to a maximum value as the drop falls. By the use of a suitable recorder to measure the current, the characteristic saw-toothed record is obtained. The limiting current is the sum of the residual and the diffusion currents. The residual current is subtracted from the limiting current to give the wave height.

Ilkovic Equation— The linear relationship between the diffusion current (id) and the concentration of electro-active species is shown by the Ilkovic equation:

$$id = 708nD1 / 2Cm2 / 3t1 / 6$$

in which id is the maximum current in microamperes; n is the number of electrons required per molecule of electro-active substance; D is its diffusion coefficient, in square cm per second; C is the concentration, in millimoles per L; m is the rate of mercury flow from the DME, in mg per second; and t is the drop time, in seconds.

Modern polarographs are equipped with recorders capable of following the current during the latter portion of the drop life; consequently, the maximum of the oscillations is the measure of the current. When the current is measured only at the end of the drop life, the technique is termed sampled dc polarography. In this case, only the maximum currents are recorded and oscillations due to drop growth are not observed.

For instruments equipped with galvanometers to measure the current or recorders operated in a damped mode, the saw-toothed waves correspond to oscillations about the average current. In the latter case, the average of the oscillations is the measure of the current. For polarograms obtained in this manner, the id given by the Ilkovic equation is the average current in microamperes observed during the life of the drop, when the coefficient 708 is replaced by 607.

Control of the Diffusion Current— The Ilkovic equation identifies the variables that must be controlled to ensure that the diffusion current is directly proportional to the concentration of electro-active material. At 25° the diffusion coefficients for aqueous solutions of many ions and organic molecules increase 1% to 2% per degree rise in temperature. Thus the temperature of the polarographic cell must be controlled to within  $\pm 0.5^{\circ}$ . The quantities m and t depend upon the dimensions of the capillary and the height of the mercury column above the electrode. Although results obtained with different capillaries can be compared if the product  $m^2/3t1/6$  is known, it is advisable to use the same capillary with a constant head of mercury during a series of analyses. The diffusion current is proportional to the square root of the height of the mercury column. A mercury reservoir with a diameter greater than 4 cm prevents any significant drop in the mercury level during a series of runs.

The capillary for the DME has a bore of approximately 0.04 mm and a length of 6 cm to 15 cm. The height of the mercury column, measured from the tip of the capillary to the top of the mercury pool, ranges from 40 cm to 80 cm. The exact length of the capillary and the height of the mercury column are adjusted to give a drop-time of between 3 and 5 seconds at open circuit with the capillary immersed in the test solution.

Equipment is available that allows controlled drop-times of fractions of a second to several seconds. As detail within a polarogram is related to the number of drops delivered during a given potential change, such short drop-times allow more rapid recording of the polarogram.

The current flowing through the test solution during the recording of a polarogram is in the microampere range. Thus, the current flow produces negligible changes in the test solution and several polarograms can be run on the same test solution without significant differences.

Half-wave Potential— The half-wave potential ( $E_{1/2}$ ) occurs at the point on the polarogram one-half the distance between the residual current and the limiting current plateau. This potential is characteristic of the electro-active species and is largely independent of its concentration or the capillary used to obtain the wave. It is dependent upon the solution composition and may change with variations in the pH or in the solvent system or with the addition of complexing agents. The half-wave potential thus serves as a criterion for the qualitative identification of a substance.

The potential of the DME is equal to the applied voltage versus the reference electrode after correction for the iR drop (that potential need to pass the current, i, through the solution with a resistance R). It is especially important to make this correction for nonaqueous solutions, which ordinarily possess high resistance, if an accurate potential for the DME is needed. Correction of the half-wave potential is not required for quantitative analysis. Unless otherwise indicated, it is to be understood that potentials represent measurements made against the SCE.

Removal of Dissolved Oxygen— Inasmuch as oxygen is reduced at the DME in two steps, first to hydrogen peroxide and then to water, it interferes where polarograms are to be made at potentials more negative than about 0 volt versus SCE, and must be removed. This may be accomplished by bubbling oxygen-free nitrogen through the solution for 10 to 15 minutes immediately before recording the wave, the nitrogen first having been "conditioned" to minimize changes due to evaporation, by being passed through a separate portion of the solution.

It is necessary that the solution be quiet and vibration-free during the time the wave is recorded, to ensure that the current is diffusion-controlled. Therefore, the nitrogen aeration should be stopped and the gas be directed to flow over the surface of the solution before a polarogram is recorded.

In alkaline media, sodium bisulfite may be added to remove oxygen, provided the reagent does not react with other components of the system.

Measurement of Wave Height— To use a polarogram quantitatively, it is necessary to measure the height of the wave. Since this is a measure of the magnitude of the diffusion current, it is measured vertically. To compensate for the residual current, the segment of the curve preceding the wave is extrapolated beyond the rise in the wave. For a well-formed wave where this extrapolation parallels the limiting current plateau, the measurement is unambiguous. For less well-defined waves, the following procedure may be used unless otherwise directed in the individual monograph. Both the residual current and the limiting current are extrapolated with straight lines, as shown by the graph (Figure 1). The wave height is taken as the vertical distance between these lines measured at the half-wave potential.

Procedure— [Caution—Mercury vapor is poisonous, and metallic mercury has a significant vapor pressure at room temperature. The work area in which mercury is used should be constructed in such a way that any spilled or spattered droplets of mercury can be completely recovered with relative ease. Scrupulously clean up mercury after each use of the instrument. Work in a well-ventilated laboratory, taking care to clean up any spilled mercury. ] Transfer a portion of the final dilution of the substance being assayed to a suitable polarographic cell immersed in a water bath regulated to  $25 \pm 0.5^{\circ}$ . Pass a stream of nitrogen through the solution for 10 to 15 minutes to remove dissolved oxygen. Start the mercury dropping from the capillary, insert the capillary into the test solution, and adjust the height of the mercury reservoir. Switch the flow of nitrogen to pass over the surface of the solution, and record the polarogram over the potential range indicated in the individual monograph, using the appropriate recorder or galvanometer sensitivity to give a suitable wave. Measure the height of the wave, and unless otherwise directed in the monograph, compare this with the wave height obtained with the appropriate USP Reference Standard, measured under the same conditions.

Pulse Polarography— In conventional dc polarography, the current is measured continuously as potential is applied as a linear ramp (see Figure 2).

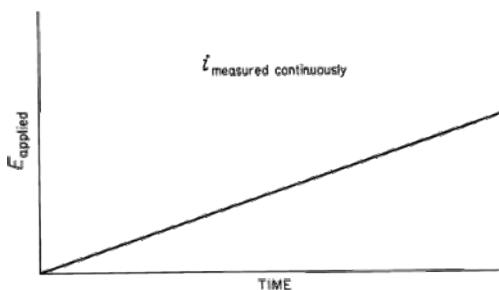

Fig. 2. Direct Current (dc) Polarography.

This current is composed of two elements. The first, the diffusion (faradaic) current, is produced by the substance undergoing reduction or oxidation at the working electrode, and is directly proportional to the concentration of this substance. The second element is the capacitative current (charging of the electrochemical double layer). The changes in these currents as the mercury drop varies in size produce the oscillations present in typical dc polarograms.

In normal pulse polarography, a potential pulse is applied to the mercury electrode near the end of the drop life, with the drop being held at the initial potential during growth period (see [Figure 3](#)).

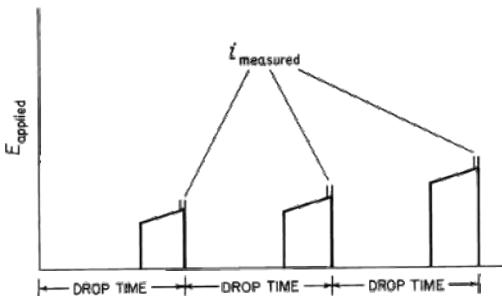

Fig. 3. Pulse Polarography.

Each succeeding drop has a slightly higher pulse applied to it, with the rate of increase being determined by the selected scan rate. The current is measured at the end of the pulse where the capacitative current is nearly zero, and thus primarily faradaic current is measured (see [Figure 4](#)).

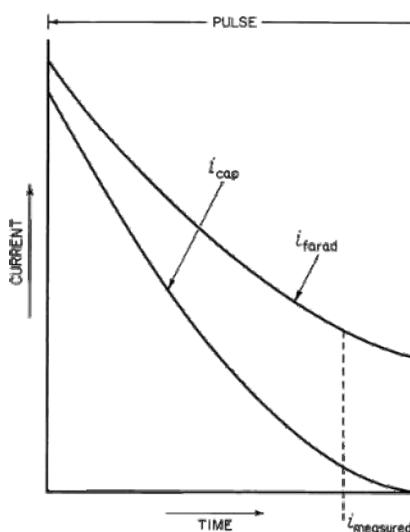

Fig. 4. Plot of Current Versus Time in Pulse Polarography.

In addition, since the pulse is applied for only a short duration, the diffusion layer is not depleted as extensively as in dc polarography and larger current levels are obtained for equivalent concentrations. Concentrations as low as  $10^{-6}$  M can be measured, providing approximately a ten-fold increase in sensitivity over that with dc polarography. Limiting current values are more easily measured, since the waves are free from oscillations.

Differential pulse polarography is a technique whereby a fixed-height pulse applied at the end of the life of each drop is superimposed on a linear increasing dc ramp (see [Figure 5](#)).

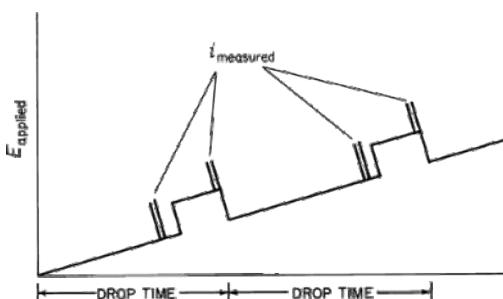

Fig. 5. Differential Pulse Polarography.

Current flow is measured just before application of the pulse and again at the end of the pulse. The difference between these two currents is measured and presented to the recorder.

Such a differential signal provides a curve approximating the derivative of the polarographic wave, and gives a peak presentation. The peak potential is equivalent to:

$$E_1 / 2 - \Delta E / 2$$

where  $\Delta E$  is the pulse height. The peak height is directly proportional to concentration at constant scan rates and constant pulse heights. This technique is especially sensitive (levels of  $10^{-7}M$  may be determined) and affords improved resolution between closely spaced waves.

**Anodic Stripping Voltammetry**— Anodic stripping voltammetry is an electrochemical technique whereby trace amounts of substances in solution are concentrated (reduced) onto an electrode and then stripped (oxidized) back into solution by scanning the applied voltage anodically. The measurement of the current flow as a function of this voltage and scanning rate provides qualitative and quantitative information on such substances. The concentration step permits analyses at  $10^{-7}M$  to  $10^{-9}M$  levels.

Basic instrumentation includes a voltage ramp generator; current-measuring circuitry; a cell with working, reference, and counter electrodes; and a recorder or other read-out device. Instruments having dc or pulse-polarographic capabilities are generally quite adequate for stripping application. The working electrode commonly used is the hanging mercury drop electrode (HMDE), although the mercury thin-film electrode (MTFE) has acquired acceptance. For analysis of metals such as silver, platinum, and gold, whose oxidation potentials are more positive than mercury, and mercury itself, the use of solid electrodes such as platinum, gold, or carbon is required. A saturated calomel electrode or a silver–silver chloride electrode serves as the reference except for the analysis of mercury or silver. A platinum wire is commonly employed as the counter electrode.

Test specimens containing suitable electrolyte are pipeted into the cell. Dissolved oxygen is removed by bubbling nitrogen through the cell for 5 to 10 minutes.

Generally, an electrolysis potential equivalent to 200 to 300 mV more negative than the half-wave potential of the material to be analyzed is applied (although this potential is to be determined experimentally), with stirring for 1 to 10 minutes. For reproducible results, maintain constant conditions (i.e., deposition time, stirring rate, temperature, specimen volume, and drop size if HMDE is used).

After deposition, the stirring is discontinued and the solution and electrode are allowed to equilibrate for a short period. The potential is then rapidly scanned anodically (10 mV/second or greater in dc polarography and 5 mV/second in differential pulse polarography). As in polarography, the limiting current is proportional to concentration of the species (wave height in dc and pulse; peak height in differential pulse), while the half-wave potential (dc, pulse) or peak potential (differential pulse) identifies the species. It is imperative that the choice of supporting electrolyte be made carefully in order to obtain satisfactory behavior. Quantitation is usually achieved by a standard addition or calibration method.

This technique is appropriate for trace-metal analysis, but has limited use in organic determinations, since many of these reactions are irreversible. In analyzing substances such as chloride, cathodic stripping voltammetry may be used. The technique is the same as anodic stripping voltammetry, except that the substance is deposited anodically and then stripped by a cathodic voltage scan.

#### 811 POWDER FINENESS

Test procedures for sieving powder materials are described under [Particle Size Distribution Estimation by Analytical Sieving](#) (786), and, where practical, the particle size distribution should be estimated by this procedure. The classification of powder fineness in this Pharmacopeia, expressed in descriptive terms, is provided in the table. For practical reasons, sieves are the preferred means of measuring powder fineness for most pharmaceutical purposes. Sieving is most suitable where a majority of the particles are larger than about 75  $\mu\text{m}$ , although it can be used for some powders having smaller particle sizes where the method can be validated. Avoid processing conditions that would alter the true particle size distribution of the powder being tested.

**Sieves for Pharmacopeial Testing**— Sieves for Pharmacopeial testing are described under [Particle Size Distribution Estimation by Analytical Sieving](#) (786).

**Powdered Vegetable and Animal Drugs**— In determining the powder fineness of a vegetable or animal drug, no portion of the drug may be rejected during milling or sifting unless specifically permitted in the individual monograph.

**Air Permeation Method for Determining Fineness of Sub-sieve Size Particles**— The average particle size measured is in the range of 0.2 to 50  $\mu\text{m}$ . The test specimen is loaded into a precision bore tube and is compacted between two paper disks and porous plugs by a rack-and-pinion packing plunger. The determination of the particle size of the specimen in the uniformly packed column is based on its resistance to the flow of a closely regulated current of dried air. The liquid level of a flowmeter-manometer corresponds directly to particle size. Special handling instructions and procedures are provided in the individual monographs.

**Classification of Powder Fineness**— Powder fineness may be classified by determining the smallest sieve opening through which a specified quantity of material passes. Results are typically reported as the following:

- d90 = smallest sieve opening through which 90% or more of the material passes
- d50 = smallest sieve opening through which 50% or more of the material passes
- d10 = smallest sieve opening through which 10% or more of the material passes.

The upper and lower limit of the sieve opening values may be reported when results of two or more test lots are combined, e.g., "Lot A has a d50 value of 1000  $\mu\text{m}$  with a range 850–1180  $\mu\text{m}$ ."

An alternative but less informative method of classifying powder fineness is by use of the terms in the following table.

Classification of Powders by Fineness	
Classification of Powder	d50 Sieve Opening ( $\mu\text{m}$ )
Very Coarse	> 1000
Coarse	355–1000
Moderately Fine	180–355
Fine	125–180
Very Fine	90–125

### 821 RADIOACTIVITY

Radioactive pharmaceuticals require specialized techniques in their handling and testing in order that correct results may be obtained and hazards to personnel be minimized. All operations should be carried out or supervised by personnel having had expert training in handling radioactive materials.

The facilities for the production, use, and storage of radioactive pharmaceuticals are generally subject to licensing by the federal Nuclear Regulatory Commission, although in certain cases this authority has been delegated to state agencies. The federal Department of Transportation regulates the conditions of shipment of radioactive materials. State and local agencies often have additional special regulations. Each producer or user must be thoroughly cognizant of the applicable regulations of the federal Food, Drug, and Cosmetic Act, and any additional requirements of the U. S. Public Health Service and of state and local agencies pertaining to the articles concerned.

Definitions, special considerations, and procedures with respect to the Pharmacopeial monographs on radioactive drugs are set forth in this chapter.

#### GENERAL CONSIDERATIONS

##### Fundamental Decay Law

The decay of a radioactive source is described by the equation:

$$N_t = N_0 e^{-\lambda t}$$

in which  $N_t$  is the number of atoms of a radioactive substance at elapsed time  $t$ ,  $N_0$  is the number of those atoms when  $t = 0$ , and  $\lambda$  is the transformation or decay constant, which has a characteristic value for each radionuclide. The half-life,  $T_{1/2}$ , is the time interval required for a given activity of a radionuclide to decay to one-half of its initial value, and is related to the decay constant by the equation:

$$T_{1/2} = \frac{0.69315}{\lambda}$$

The activity of a radioactive source ( $A$ ) is related to the number of radioactive atoms present by the equation:

$$A = \lambda N$$

from which the number of radioactive atoms at time  $t$  can be computed, and hence the mass of the radioactive material can be determined.

The activity of a pure radioactive substance as a function of time can be obtained from the exponential equation or from decay tables, or by graphical means based on the half-life (see [Normalized Decay Chart, Figure 1](#)).

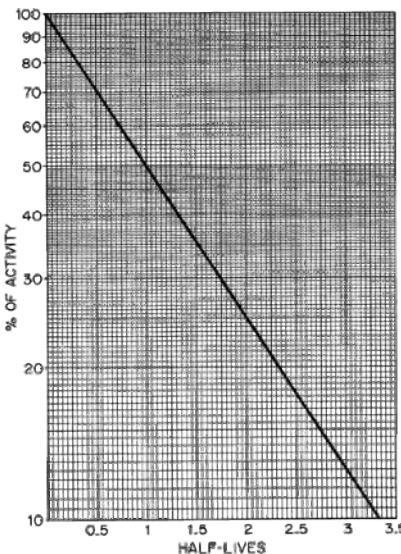

Fig. 1. Normalized Decay Chart.

The activity of a radioactive material is expressed as the number of nuclear transformations per unit time. The fundamental unit of radioactivity, the curie (Ci), is defined as  $3.700 \times 10^{10}$  nuclear transformations per second. The millicurie (mCi) and microcurie ( $\mu$ Ci) are commonly used subunits. The "number of nuclear transformations per unit time" is the sum of rates of decay from all competing modes of disintegration of the parent nuclide. Before the activity of any given radionuclide in a measured specimen can be expressed in curies, it is often necessary to know the abundance(s) of the emitted radiation(s) measured.

#### Geometry

The validity of relative calibration and measurement of radionuclides is dependent upon the reproducibility of the relationship of the source to the detector and its surroundings. Appropriate allowance must be made for source configuration.

#### Background

Cosmic rays, radioactivity present in the detector and shielding materials, and radiation from nearby radioactive sources not properly shielded from the measuring equipment, all contribute to the background count rate. All radioactivity measurements must be corrected by subtracting the background count rate from the gross count rate in the test specimen.

#### Statistics of Counting

Since the process of radioactive decay is a random phenomenon, the events being counted form a random sequence in time. Therefore, counting for any finite time can yield only an estimate of the true counting rate. The precision of this estimate, being subject to statistical fluctuations, is dependent upon the number of counts accumulated in a given measurement and can be expressed in terms of the standard deviation  $\sigma$ . An estimate for  $\sigma$  is

$$\sqrt{n}$$

where  $n$  is the number of counts accumulated in a given measurement. The probability of a single measurement falling within

$$\pm 100/\sqrt{n}\%$$

of the mean of a great many measurements is 0.68. That is, if many measurements of  $n$  counts each were to be made, approximately two-thirds of the observations would lie within

$$\pm 100/\sqrt{n}\%$$

of the mean, and the remainder outside.

Because of the statistical nature of radioactive decay, repeated counting of an undisturbed source in a counting assembly will yield count-rate values in accordance with the frequency of a normal distribution. Deviations in these values from the normal distribution conform to the  $\chi^2$  test. For this reason, the  $\chi^2$  test is frequently applied to determine the performance and correct operation of a counting assembly. In the selection of instruments and conditions for assay of radioactive sources, the figure of merit  $E^2/B$  should be maximized (where  $E$  = counter efficiency = observed count rate/sample disintegration rate, and  $B$  = background count rate).

#### Counting Losses

The minimum time interval that is required for the counter to resolve two consecutive signal pulses is known as the dead time. The dead time varies typically from the order of microseconds for proportional and scintillation counters, to hundreds of microseconds for Geiger-Müller counters. Nuclear events occurring within the dead time of the counter will not be registered. To obtain the corrected count rate,  $R$ , from the observed count rate,  $r$ , it is necessary to use the formula:

$$R = \frac{r}{1 - r\tau}$$

in which  $\tau$  is the dead time. The foregoing correction formula assumes a nonextendable dead time. Thus, for general validity, the value of  $r\tau$  should not exceed 0.1. The observed count rate,  $r$ , refers to the gross specimen count rate and is not to be corrected for background before use in the foregoing equation.

#### Calibration Standards

Perform all radioactivity assays using measurement systems calibrated with appropriately certified radioactivity standards. Such calibration standards may be purchased either direct from the National Institute of Standards and Technology or from other sources that have established traceability to the National Institute of Standards and Technology through participation in a program of inter-comparative measurements. Where such calibration standards are unavailable, the Pharmacopelia provides the nuclear decay data required for calibration. These data, as well as half-life values, are obtained from the Evaluated Nuclear Structure Data File of the Oak Ridge Nuclear Data Project, and reflect the most recent values at the time of publication.

#### Carrier

The total mass of radioactive atoms or molecules in any given radioactive source is directly proportional to the activity of the radionuclide for a given half-life, and the amount present in radiopharmaceuticals is usually too small to be measured by ordinary chemical or physical methods. For example, the mass of  $^{131}\text{I}$  having an activity of 100 mCi is  $8 \times 10^{-7}$  g. Since such small amounts of material behave chemically in an anomalous manner, carriers in the form of nonradioactive isotopes of the same radionuclide may be added during processing to permit ready handling. In many cases, adsorption can be prevented merely by increasing the hydrogen-ion concentration of the solution. Amounts of such material, however, must be sufficiently small that undesirable physiological effects are not produced. The term "carrier-free" refers only to radioactive preparations in which nonradioactive isotopes of the radionuclide are absent. This implies that radioactive pharmaceuticals produced by means of  $(n, \gamma)$  reactions cannot be considered carrier-free.

The activity per unit volume or weight of a medium or vehicle containing a radionuclide either in the carrier-free state or in the presence of carrier is referred to as the radioactive concentration, whereas the term specific activity is used to express the activity of a radionuclide per gram of its element.

#### Radiochemical Purity

Radiochemical purity of a radiopharmaceutical preparation refers to the fraction of the stated radionuclide present in the stated chemical form. Radiochemical impurities in radiopharmaceuticals may result from decomposition and from improper preparative procedures. Radiation causes decomposition of water, a main ingredient of most radiopharmaceuticals, leading to the production of reactive hydrogen atoms and hydroxyl radicals, hydrated electrons, hydrogen, hydrogen ions, and hydrogen peroxide. The last-mentioned is formed in the presence of oxygen radicals, originating from the radiolytic decomposition of dissolved oxygen. Many radiopharmaceuticals show improved stability if oxygen is excluded. Radiation may also affect the radiopharmaceutical itself, giving rise to ions, radicals, and excited states. These species may combine with one another and/or with the active species formed from water. Radiation decomposition may be minimized by the use of chemical agents that act as electron or radical scavengers. Electrons trapped in solids cause discoloration due to formation of F-centers and the darkening of glass containers for radiopharmaceuticals, a situation that typifies the case. The radiochemical purity of radiopharmaceuticals is determined by column, paper, and thin-layer chromatography or other suitable analytical separation techniques as specified in the individual monograph.

#### Radionuclidic Purity

Radionuclidic purity of a radiopharmaceutical preparation refers to the proportion of radioactivity due to the desired radionuclide in the total radioactivity measured. Radionuclidic purity is important in the estimation of the radiation dose received by the patient when the preparation is administered. Radionuclidic impurities may arise from impurities in the target materials, differences in the values of various competing production cross-sections, and excitation functions at the energy or energies of the bombarding particles during production.

#### Terms and Definitions

The date of manufacture is the date on which the manufacturing cycle for the finished product is completed.

The date of assay is the date (and time, if appropriate) when the actual assay for radioactivity is performed.

The date of calibration is an arbitrary assigned date and time to which the radioactivity of the product is calculated for the convenience of the user.

The expiration date is the date that establishes a limit for the use of the product. The expiration period (i.e., the period of time between the date of manufacture and the expiration date) is based on a knowledge of the radioactive properties of the product and the results of stability studies on the finished dosage form.

#### Labeling

Individual radiopharmaceutical monographs indicate the expiration date, the calibration date, and the statement, "Caution—Radioactive Material." The labeling indicates that in making dosage calculations, correction is to be made for radioactive decay, and also indicates the radioactive half-life of the radionuclide. Articles that are Injections comply with the requirements for Labeling under [Injections \(1\)](#), and those that are Biologics comply with the requirements for Labeling under [Biologics \(104\)](#).

#### IDENTIFICATION AND ASSAY OF RADIONUCLIDES

##### Instrumentation

##### ionization chambers

An ionization chamber is an instrument in which an electric field is applied across a volume of gas for the purpose of collecting ions produced by a radiation field. The positive ions and negative electrons drift along the lines of force of the electric field, and are collected on electrodes, producing an ionization current. In a properly designed well-type ionization chamber, the ionization current should not be too dependent on the position of the radioactive specimen, and the value of the current per unit activity, known as the calibration factor, is characteristic of each gamma-ray-emitting radionuclide.

The ionization current produced in an ionization chamber is related to the mean energy of the emitted radiation and is proportional to the intensity of the radiation. If standard sources of known disintegration rates are used for efficiency calibration, the ionization chamber may then be used for activity determinations between several microcuries and several hundred

...licures or more. The upper limit of activity that may be measured in an ionization chamber usually is not sharply defined and may be limited by saturation considerations, range of the amplifier, and design of the chamber itself. The data supplied with or obtained from a particular instrument should be reviewed to ascertain the useful ranges of energies and intensities of the device.

Reproducibility within approximately 5% or less can be readily obtained in about 10 seconds, with a deep re-entrant well-type chamber. The most commonly used form of ionization chamber for measurement of the activities of radiopharmaceuticals is known as a dose calibrator.

Although the calibration factor for a radionuclide may be interpolated from an ionization chamber energy-response curve, there are a number of sources of error possible in such a procedure. It is therefore recommended that all ionization chamber calibrations be performed with the use of authentic reference sources of the individual radionuclides, as described hereinafter.

The calibration of a dose calibrator should be maintained by relating the measured response of a standard to that of a long-lived performance standard, such as radium 226 in equilibrium with its daughters. The instrument must be checked daily with the 226Ra or other source to ascertain the stability over a long period of time. This check should include performance standard readings at all radionuclide settings employed. To obtain the activity ( $A_x$ ) of the radionuclide being measured, use the relationship:

$$A_x = \frac{R_x R}{R_n}$$

in which  $R_n$  is the new reading for the radium or other source,  $R_c$  is the reading for the same source obtained during the initial calibration procedure, and  $R$  is the observed reading for the radionuclide specimen. Obviously, any necessary corrections for radioactive decay of the reference source must first be applied. Use of this procedure should minimize any effects due to drift in the response of the instrument. The recommended activity of the 226Ra or other monitor used in the procedure described above is 75 to 150  $\mu\text{Ci}$ . It is recommended also that the reproducibility and/or stability of multirange instruments be checked for all ranges with the use of appropriate standards.

The size and shape of a radioactive source may affect the response of a dose calibrator, and it is often necessary to apply a small correction when measuring a bulky specimen.

#### scintillation and semiconductor detectors

When all or part of the energy of beta or gamma radiation is dissipated within scintillators, photons of intensity proportional to the amount of dissipated energy are produced. These pulses are detected by an electron multiplier phototube and converted to electrical pulses, which are subsequently analyzed with a pulse-height analyzer to yield a pulse-height spectrum related to the energy spectrum of the radiation emitted by the source. In general, a beta-particle scintillation pulse-height spectrum approximates the true beta-energy spectrum, provided that the beta-particle source is prepared in such a manner that self-absorption is minimized. Beta-ray spectra may be obtained by using calcium fluoride or anthracene as the scintillator, whereas gamma-ray spectra are usually obtained with a thallium-activated sodium iodide crystal or a large-volume lithium-drifted germanium semiconductor detector. The spectra of charged particles also may be obtained using silicon semiconductor detectors and/or gas proportional counters. Semiconductor detectors are in essence solid-state ionization chambers, but the energy required to create an electron-hole pair or to promote an electron from the valence band to the conduction band in the semiconductor is about one-tenth the energy required for creation of an ion-pair in a gas-filled ionization chamber or proportional counter and is far less than the energy needed to produce a photon in a NaI(Tl) scintillation crystal. In gamma-ray spectrometry, a Ge(Li) detector can yield an energy resolution of 0.33% for 1.33 MeV gamma-rays from  $^{60}\text{Co}$ , while a 3- x 3-inch NaI(Tl) crystal can give a value of 5.9% for the same gamma-ray energy. The energy resolution is a measure of the ability to distinguish the presence of two gamma rays closely spaced in energy and is defined by convention as the full width of the photopeak at its half maximum (FWHM), expressed in percentage of the photopeak energy.

Gamma-ray spectra exhibit one or more sharp, characteristic photopeaks, or full-energy peaks, as a result of total absorption in the detector of the full energy of gamma radiations from the source; these photopeaks are useful for identification purposes. Other secondary peaks are observed as a consequence of backscatter, annihilation radiation, coincidence summing, fluorescent X-rays, etc., accompanied by a broad band known as the Compton continuum arising from scattering of the photons in the detector and from surrounding materials. Since the photopeak response varies with gamma-ray energy, calibration of a gamma-ray spectrometer should be achieved with radionuclide standards having well-known gamma-ray energies and emission rates. The shape of the gamma-ray spectrum is dependent upon the shape and size of the detector and the types of shielding materials used.

When confirming the identity of a radionuclide by gamma-ray spectrometry, it is necessary to make a comparison of the specimen spectrum with that of a specimen of known purity of the same radionuclide obtained under identical instrument parameters and specimen geometry. Where the radionuclides emit coincident X- or gamma-radiations, the character of the pulse-height distribution often changes quite dramatically because of the summing effect of these coincident radiations in the detector as the efficiency of detection is increased (e.g., by bringing the source closer to the detector). Such an effect is particularly evident in the case of iodine 125. Among the more useful applications of gamma-ray spectrometry are those for the identification of radionuclides and the determination of radionuclidic impurities.

Where confirmation of the identity of a given radionuclide by means of a direct comparison with the spectrum of a specimen of the same radionuclide of known purity is not possible, the identity of the radionuclide in question must then be established by the following method. Two or more of the following nuclear decay scheme parameters of the radionuclide specimen to be identified shall be measured, and agreement shall be within  $\pm 10\%$ : (1) half-life, (2) energy of each gamma- or X-ray emitted, (3) the abundance of each emission, and (4)  $E_{\text{max}}$  for those radionuclides that decay with beta-particle emissions. Such measurements are to be performed as directed in the Identification and Assay sections of this chapter.

Agreement of two or more of the measured parameters with the corresponding published nuclear decay scheme data constitutes confirmation of the identity of the radionuclide.

#### liquid-scintillation counters

Alpha- and beta-emitting radionuclides may be assayed with the use of a liquid-scintillation detector system. In the liquid scintillator, the radiation energy is ultimately converted into light quanta that are usually detected by two multiplier phototubes so arranged as to count only coincidence radiation. The liquid scintillator is a solution consisting of a solvent, primary and secondary solutes, and additives. The charged particle dissipates its energy in the solvent, and a fraction of this energy is converted into fluorescence in the primary solute. The function of the secondary solute is to shift the fluorescence radiation to longer wavelengths that are more efficiently detected by the multiplier phototubes. Frequently used solvents are toluene and p-xylene; primary solutes are 2,5-diphenyloxazole (PPO) and 2-(4'-tert-butylphenyl)-5-(4-biphenyl)-1,3,4-oxadiazole (butyl-PBD); and secondary solutes are 2,2'-p-phenylenebis[4-methyl-5-phenyloxazole] (dimethyl-POPOP) and p-bis(o-methylstyryl)benzene (bis-MSB). As a means of attaining compatibility and miscibility with aqueous specimens to be assayed, many additives, such as surfactants and solubilizing agents, are also incorporated into the scintillator. For an accurate determination of radioactivity of the specimen, care must be exercised to prepare a specimen that is truly homogeneous. The presence of impurities or color in solution causes a decrease in photon output of the scintillator; such a decrease is known as quenching. Accurate radioactivity measurement requires correcting for count-rate loss due to quenching.

The disintegration rate of a beta-particle source may be determined by a procedure in which the integral count rate of the specimen is measured as a function of the pulse-height discriminator bias, and the emission rate is then obtained by extrapolation to zero bias. Energetic alpha-particle emitters may be similarly measured by this method.

#### Identification

A radionuclide can be identified by its mode of decay, its half-life, and the energies of its nuclear emissions.

The radioactive half-life is readily determined by successive counting of a given source of the radionuclide over a period of time that is long compared to its half-life. The response of the counting assembly when employed for the decay measurement of long-lived radionuclides should be monitored with an even longer-lived reference source to assess and

compensate for errors arising from electronic drift. In the case of short-lived radionuclides, when the counting period constitutes a significant fraction of the half-life of the radionuclide, the recorded count rate must be corrected to the time when the count is initiated, as follows:

$$R_t = \frac{r\lambda t}{1 - e^{-\lambda t}}$$

in which  $R_t$  is the count rate at the beginning of a counting period,  $r$  is the count rate observed over the entire counting period,  $t$  is the duration of the counting period,  $\lambda$  is the decay constant of the radionuclide, and  $e$  is the base of the natural logarithm. When  $t$  is small compared to the half-life of the radionuclide under study so that  $\lambda t < 0.05$ , then  $(1 - e^{-\lambda t})$  approaches  $\lambda t$ , and no such correction is necessary.

The energy of nuclear emissions is often determined by the maximum range of penetration of the radiation in matter (in the case of alpha- and beta-particles) and by the full-energy peak or photopeak in the gamma-ray spectrum (in the case of X- and gamma-rays). Since beta-particles are emitted with a continuous energy spectrum, the maximum beta-energy,  $E_{max}$ , is a unique index for each beta-emitting radionuclide. In addition to the maximum range and energy spectrum of the beta-particles, the absorption coefficient, when obtained under reproducible counting conditions, can serve as a reliable index for identification of a beta-emitter. Fortunately, beta-particles are absorbed in matter in an approximately exponential manner, and a plot of the logarithm of the beta-particle count rate as a function of the absorber thickness is known as the absorption curve. The initial portion of the absorption curve shows linearity from which the absorption coefficient can be obtained. The maximum range is determined by the use of absorbers of varying thickness, and the energy spectrum is measured by beta-ray scintillation spectrometry.

The absorption of gamma-rays in matter is strictly exponential, but the half-value layers of attenuation have not been very useful for the purpose of radionuclide characterization. Gamma-rays from each isomeric transition are mono-energetic; their energy can be directly measured by gamma-ray spectrometry. Because of their high energy resolution, solid-state detectors [Ge(Li)] are vastly superior to scintillation detectors [NaI(Tl)] in gamma-ray spectrometry.

The activities of radiopharmaceutical solutions are frequently in the range of millicuries per mL. Such solutions usually must be extensively diluted before they can be accurately assayed. The diluent should be compatible with the radiopharmaceutical with respect to factors such as pH and redox potentials, so that no hydrolysis or change in oxidation state occurs upon dilution, which could lead to adsorption and separation of the radionuclide from solution.

#### beta-emitting radionuclides

Mass Absorption Coefficient Procedure— Deposit and dry an aliquot of the radioactive phosphorus 32 solution on a thin plastic film to minimize backscattering, and place it under a suitable counter. Determine the counting rates successively, using not less than six different "thicknesses" of aluminum each between 20 and 50 mg/cm2 and a single absorber thicker than 800 mg/cm2, which is used to measure the background. (The absorbers are inserted between the test specimen and the counter but are placed nearer the counter window to minimize scattering.) Net beta-particle count rates are obtained after subtraction of the count rate found with the absorber having a thickness of 800 mg/cm2 or greater. Plot the logarithm of the net beta-particle count rate as a function of the total absorber "thickness." The total absorber "thickness" is the "thickness" of the aluminum absorbers plus the "thickness" of the counter window (as stated by the manufacturer) plus the air-equivalent "thickness" (the distance in centimeters of the specimen from the counter window multiplied by

1.205 mg/cm3 at 20° and 76 cm of mercury), all expressed in mg/cm2. An approximately straight line results.

Choose two total absorber "thicknesses" that differ by 20 mg/cm2 or more and that fall on the linear plot, and calculate the mass absorption coefficient,  $\mu$ , by the equation:

$$\mu = \frac{1}{t_2 - t_1} \cdot \ln \left( \frac{N_{t_1}}{N_{t_2}} \right) = \frac{2.303}{t_2 - t_1} (\log N_{t_1} - \log N_{t_2})$$

in which  $t_1$  and  $t_2$  represent the total absorber "thicknesses," in mg/cm2,  $t_2$  being the thicker absorber, and  $N_{t_1}$  and  $N_{t_2}$  being the net beta-particle rates with the  $t_1$  and  $t_2$  absorbers, respectively.

For characterization of the radionuclide, the mass absorption coefficient should be within  $\pm 5\%$  of the value found for a pure specimen of the same radionuclide when determined under identical counting conditions and geometry.

Other Methods of Identification— Other methods for determining the identity of a beta emitter also rely upon the determination of  $E_{max}$ . This may be accomplished in several ways. For example, (1) utilization of the range energy relationships of beta particles in an absorber, or (2) determination of  $E_{max}$  from a beta-particle spectrum obtained on an energy-calibrated beta-spectrometer using a thin source of the radionuclide (see Scintillation and Semiconductor Detectors in this chapter).

#### gamma-emitting radionuclides

The gamma-ray spectrum of a radionuclide is a valuable tool for the qualitative identification of gamma-ray emitting radionuclides. The full-energy peak, or the photopeak, is identified with the gamma-ray transition energy that is given in the decay scheme of the radionuclide.

In determining radionuclidic identity and purity, the gamma-ray spectrum of a radioactive substance is obtained with either a NaI(Tl) crystal or a semiconductor Ge(Li) detector. The latter has an energy resolution more than an order of magnitude better than the former and is highly preferred for analytical purposes. The spectrum obtained shall be identical in shape to that of a specimen of the pure radionuclide, measured with the same detection system and in the same geometry. The gamma-ray spectrum of the radiopharmaceutical shall contain only photopeaks identifiable with the gamma-ray transition energies found in the decay scheme of the same radionuclide. For low geometrical efficiencies, the areas under the photopeaks, after correction for the measured detector efficiency, shall be proportional to the abundances or emission rates of the respective gamma-rays in the radionuclide.

#### radionuclidic impurities

Because they are extremely toxic, alpha-emitting nuclides must be strictly limited in radiopharmaceutical preparations. Procedures for identifying beta- and gamma-active radionuclides as given in the foregoing text are applicable to the detection of gamma and usually beta contaminants.

The gross alpha-particle activity in radiopharmaceutical preparations can be measured by the use of a windowless proportional counter or a scintillation detector employing a silver-activated zinc-sulfide phosphor or by the techniques of liquid-scintillation counting.

The heavy ionization caused by alpha particles allows the measurement of alpha-emitting radionuclides in the presence of large quantities of beta- and gamma-active nuclides by the use of appropriate techniques for discriminating the amplitudes of signal pulses. In proportional counting, the operating voltage region for counting alpha particles, referred to as the "alpha plateau," is considerably lower than the "beta plateau" for counting beta and gamma radiations. Typical "alpha plateau" and "beta plateau" voltage settings with P-10 counting gas are 900 to 1300 and 1600 to 2000 volts, respectively.

When silver-activated zinc-sulfide phosphor is employed for alpha-particle detection, the alpha particles can be distinguished from other interfering radiation by pulse-height discrimination. Care must be exercised to minimize self-absorption at the source whenever specimens are prepared for alpha-particle counting.

#### Assay

#### beta-emitting radionuclides

Procedure— The disintegration rate (A) of a beta-particle-emitting specimen is obtained by counting a quantitatively deposited aliquot in a fixed geometry according to the formula:

$$A = \frac{R}{\epsilon \times f_r \times f_b \times f_s}$$

in which  $\epsilon$  is the counting efficiency of the counter;  $f_r$  is the correction factor for counter dead time;  $f_b$  is the correction factor for backscatter; and  $f_s$  is the correction factor for self-absorption. The count rate for zero absorber is obtained by extrapolation of the initial linear portion of the absorption curve to zero absorber "thickness," taking into consideration the  $\text{mg/cm}^2$  "thickness" of specimen coverings, counter window, and the intervening air space between specimen and the counter window. The counter efficiency,  $\epsilon$ , is determined by use of a long-lived secondary standard with similar spectral characteristics. RaD + E has frequently been used for efficiency calibration of counters for phosphorus 32. By the use of identical measurement conditions for the specimen and the standard (and extrapolation to zero absorber), the ratio of the values of  $f_r$ ,  $f_b$ , and  $f_s$  for the standard and the specimen approaches unity.

The previous relationship is valid also when the counter has been calibrated with a standard of the radionuclide to be assayed. In this case, however, the extrapolations to zero absorber "thickness" for the specimen and standard are not required, as the two absorption corrections cancel for a given geometry.

Another useful and frequently employed method for the determination of the disintegration rate of beta-emitting radionuclides is liquid-scintillation counting, which also utilizes an extrapolation of the specimen count rate to zero pulse-height discriminator bias.

#### gamma-emitting radionuclides

For the assay of gamma-emitting radionuclides, three methods are provided. The selection of the preferred method is dictated by the availability of a calibration standard of the radionuclide to be assayed and the radionuclitic purity of the article itself.

Direct comparison with a calibration standard is required if a calibration standard of the radionuclide to be assayed is available and if the upper limit of conceivable error in the activity determination arising from the presence of radionuclitic impurities has been determined to be less than 3%. If the required calibration standard is not routinely available, as would probably be the case for a short-lived radionuclide, but was available at some time prior to the performance of the assay for determination of efficiency of the counting system for the radionuclide to be assayed, use a calibrated counting system, provided the radionuclitic impurity content of the specimen meets the requirements stated for the direct comparison method. If the requirements for either of the first two methods cannot be met, use the method for determination of activity from a calibration curve.

With the exception of the first method, the counting systems used are monitored for stability. This requirement is met by daily checks with a long-lived performance check source and weekly checks with at least three sources covering a broad range of gamma-ray emission energies (e.g., 57Co, 137Cs, and 60Co). If a discrepancy for any of the aforementioned measurements is found, either completely recalibrate or repair and recalibrate the system prior to further use.

**Assay by Direct Comparison with a Calibration Standard**— An energy selective measurement system (e.g., pulse-height analyzer) is not required for this procedure. Use either an ionization chamber or an integral counting system with a NaI(Tl) detector. A consistently reproducible geometrical factor from specimen to specimen is essential for accurate results.

With proper precautions, the accuracy of this method approaches the accuracy with which the disintegration rate of the calibration standard is known.

Determine the counting rate of the detector system for a calibration standard of the radionuclide to be assayed (e.g., active enough to give good measurement statistics in a reasonable time, but not so active as to cause serious dead-time problems), selecting such a standard as to provide optimum accuracy with the particular assembly used. Place an accurately measured aliquot of the unknown assay specimen (diluted, if necessary) in a container identical to that used for the standard, and measure this specimen at approximately the same time and under the same geometrical conditions as for the standard. If the elapsed time between the measurements of the calibration standard and the specimen exceeds 12 hours, check the stability of the measurement system within 8 hours of the specimen measurement time with a long-lived performance check source. Record the system response with respect to the same check source at the time of calibration, and if subsequent checks exceed the original recorded response by more than  $\pm 3\%$ , recalibration is required. Correct both activity determinations for background, and calculate the activity, in  $\mu\text{Ci}$  per mL, by the formula:

$$SD(g/b)$$

in which  $S$  is the  $\mu\text{Ci}$  strength of the standard,  $D$  is the dilution factor, and  $g$  and  $b$  are the measured values of counting rate for the specimen and the standard, respectively.

**Assay with a Calibrated Integral Counting System**— The procedure and precautions given for the preceding direct-comparison method apply, except that the efficiency of the detector system is determined and recorded for each radionuclide to be assayed, rather than simply recording the counting rate of the standard. Thus, the efficiency for a given radionuclide,  $x$ , is determined by  $\epsilon_x = bx/sx$ , in which  $bx$  is the counting rate, corrected for background and dead-time, for the calibration standard of the radionuclide,  $x$ , and  $sx$  is the corresponding activity of the certified calibration standard in nuclear transformations per second. For subsequent specimen assays, the activity is given by the formula:

$$A_x = Dg_x/\epsilon_x$$

in which  $D$  is the dilution factor,  $g_x$  is the specimen counting rate (corrected for background and dead-time), and  $\epsilon_x$  is the corresponding efficiency for the radionuclide.

**Determination of Activity from a Calibration Curve**— Versatility in absolute gamma-ray intensity measurements can be achieved by employing multi-channel pulse-height analysis. The photopeak efficiency of a detector system can be determined as a function of gamma-ray energy by means of a series of gamma-ray emission rate standard specimens, and the gamma-ray emission rate of any radionuclide for which no standard is available can be determined by interpolation from this efficiency curve. However, exercise care to ensure that the efficiency curve for the detector system is adequately defined over the entire region of interest by using a sufficient number of calibration points along the photopeak-energy axis.

**Selection of a Counting Assembly**— A gamma-ray spectrometer is used for the identification of radionuclides that emit X-rays or gamma rays in their decay. Requirements for an assembly suitable for identification and assay of the radionuclides used in radiopharmaceuticals are that (a) the resolution of the detector based on the 662-keV photopeak of 137Cs-137mBa must be 8.0% or better, (b) the detector must be equipped with a specimen holder designed to facilitate exact duplication of counting geometry, and (c) the pulse-height analyzer must have enough channels to delineate clearly the photopeak being observed.

**Procedure**— Minimal requirements for the maintenance of instrument calibrations shall consist of weekly performance checks with a suitable reference source and a complete recalibration semi-annually. Should the weekly performance check deviate from the value determined at the time of calibration by more than 4.0%, a complete recalibration of the instrument is required at that time.

This method involves three basic steps, namely photopeak integration, determination of the photopeak efficiency curve, and calculation of the activity of the specimen.

**photopeak integration**— The method for the determination of the required photopeak area utilizes a Gaussian approximation for fitting the photopeak. A fixed fraction of the total

number of photopeak counts can be obtained by taking the peak width,  $a$ , at some fraction of the maximum, where the shape has been experimentally found to be very close to Gaussian, and multiplying by the counting rate of the peak channel,  $P$ , after correction for any Compton and background contributions to the peak channel count rate. This background usually can be adequately determined by linear interpolation. This is illustrated in [Figure 2](#).

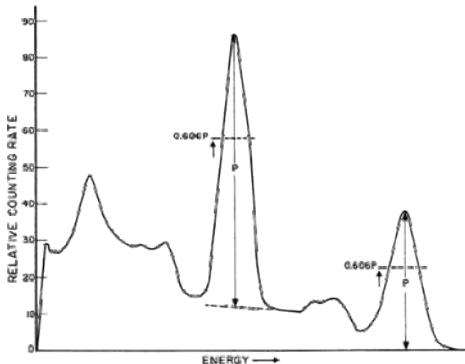

Fig. 2 Typical Gamma-ray Spectrum Showing the Selection of the Peak Channel Counting Rate,  $P$ , after the Correction for Compton and Background Contributions.

The photopeak-curve shape is closest to a straight line at  $0.606P$ , and the contribution of the fractional channels to  $a$  can be accurately estimated by interpolation. Calculate  $a$  by the equation:

$$a = D' - D + \frac{d - 0.606P}{d - c} + \frac{d' - 0.606P}{d' - c'}$$

in which  $c$  and  $d$  and also  $c'$  and  $d'$  are the single channel counting rates on either side of  $0.606P$ , and  $D$  and  $D'$  are the channel numbers (locations) of  $d$  and  $d'$ , respectively. The location of the required variables on the photopeak is illustrated in [Figure 3](#).

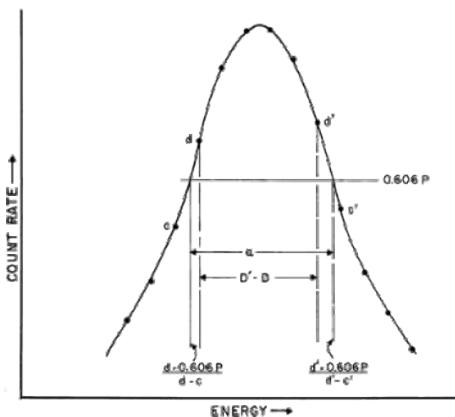

Fig. 3. Location of the Variables Required for the Determination of the Peak Width,  $a$ , at  $0.606P$ .

From the known values for the counting rate in the peak channel of the photopeak,  $P$ , and the width of the peak at  $0.606P$ ,  $a$ , a calibrated fraction of the photopeak area is then obtained from the product,  $(aP)$ .

To summarize the procedures involved in obtaining a calibrated fraction of a photopeak area using this method, the necessary steps or calculations are presented below in a stepwise manner:

(1) Subtract any Compton and background contributions from the photopeak to be measured.

(2) Determine the counting rate of the peak channel (maximum channel counting rate after subtracting Compton and background),  $P$ .

(3) Multiply  $P$  by 0.606, and locate the horizontal line corresponding to the peak width,  $a$ .

(4) Obtain the peak width,  $a$ , by inserting the values of variables (obtained as shown in the preceding figure) into the equation defining  $a$ .

(5) The desired calibrated fraction of the peak area is then equal to the product of  $a$  times  $P$  or  $F = aP$ , where  $F$  is a fractional area of the peak proportional to the emission rate of the source.

This method provides a quick and accurate means of determining the gamma-ray emission rate of sources while avoiding, to a large extent, subjective estimates of the detailed shape of the tails of the peaks. The error due to using the maximum channel counting rate, rather than the theoretical maximum or peak channel rate, is of the order of 1.0% if  $a$  is 6 or greater.

photopeak efficiency calibration— Radionuclides such as those listed in the accompanying table together with some of their nuclear decay data are available as certified reference standards.<sup>2</sup> A sufficient number of radioactive standard reference sources should be selected in order to obtain the calibration curve over the desired range. Where possible, standard sources of those radionuclides that are to be assayed should be included.

Nuclear Properties of Selected Calibration Standards<sup>(1,2)</sup>

(1) In measurements for gamma- (or X-ray) assay purposes, fluorescent radiation from lead shielding (specifically, lead K X-rays  $\sim$ 76 ke V) may interfere with quantitative results. Allowance must be made for these effects, or the radiation suppressed; a satisfactory means of absorbing this radiation is covering the exposed lead with cadmium sheet 0.06 to 0.08 inch thick, and then covering the cadmium with copper 0.02 to 0.04 inch thick.

(2) Only those photon emissions having an abundance  $\geq 1\%$  are normally included.

(3) The K notation refers to X-ray emissions.

(4) The weighted mean energies and total intensities are given for groups of photons that would not be resolved by a NaI(Tl) detector.

(5) For this photon intensity to be usable, all emitted positrons must be annihilated in the source material.

(6) Cascade.

Calculate the gamma-ray emission rate from the equation:

$$\Gamma = Asb$$

in which As is the activity, in disintegrations per second, of the standard used, and b is the number of gamma rays per disintegration at that energy. Accurately measure quantities of standard solutions of each radionuclide into identical containers, and determine the fractional photopeak area (F) for each of the standards.

Using the equation  $F_p = F/\Gamma$ , calculate the photopeak efficiency,  $F_p$ , and construct a log-log plot of  $F_p$  versus the gamma-ray energy as shown in Figure 4.

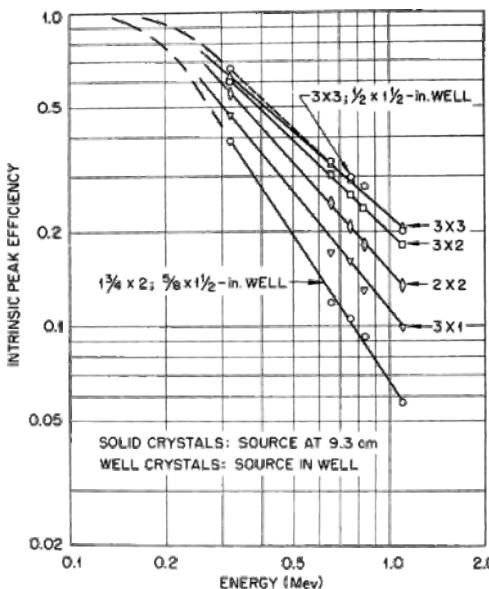

Fig. 4. Typical Photopeak Efficiency Calibration Curves for Various NaI(Tl) Detectors.

determination of specimen activity— In the same manner as in the preparation of the calibration curve, determine the fractional area (F) of the principal photopeak of the specimen under assay or an accurately measured aliquot adjusted to the same volume in an identical container as used for the standards. From the calibration curve, find the value of  $\mathcal{E}p$  for this radionuclide. Using the equation  $\Gamma = F/\mathcal{E}p$ , calculate the gamma-ray emission rate ( $\Gamma$ ). Calculate the activity (A), in disintegrations per second, of the specimen using the equation  $A = (\Gamma/b)(D)$ , in which b is the number of gamma rays per disintegration and D is the dilution factor. To obtain the activity, in  $\mu\text{Ci}$  or  $\text{mCi}$ , divide A by  $3.7 \times 10^4$  or  $3.7 \times 10^7$ , respectively. The above relationship is equally valid for obtaining the activity of an undiluted specimen or capsule; in this case, the dilution factor, D, is unity.

\* These certified reference standards are obtainable from the National Institute of Standards and Technology, Washington, DC 20234.

Auxiliary Information— Please [check for your question in the FAQs](#) before contacting USP.

823 RADIOPHARMACEUTICALS  
FOR POSITRON EMISSION  
TOMOGRAPHY—COMPOUNDING

Physicians frequently prescribe special formulations of noncommercially available drugs for patient care. Upon receipt of a prescription for such a preparation, pharmacists (or other qualified individuals working under the authority and supervision of a physician) compound the drug formulation and dispense it to the patient. For convenience, a limited bulk quantity of the special formulation may be compounded in anticipation of future dispensing requirements. Such medical and pharmacy practices are regulated by state boards of medicine and pharmacy. Physicians who prescribe a drug that must be compounded extemporaneously bear the professional responsibility to base its use on sound scientific and medical evidence.

Pharmacists and physicians who compound (or oversee the compounding of) drug preparations on prescription orders, bear the professional responsibility to ensure that the preparation meets prescribed and appropriate standards of strength, quality, and purity.

Radiopharmaceuticals administered for positron emission tomography (PET) procedures typically incorporate radionuclides that possess very short physical half-lives,  $T_{1/2}$  (e.g.,  $T_{1/2}$  of  $^{18}\text{F} = 109.7$  minutes, of  $^{11}\text{C} = 20.4$  minutes, of  $^{13}\text{N} = 9.96$  minutes, and of  $^{15}\text{O} = 2.03$  minutes). As a result, these radionuclides are usually produced using particle acceleration techniques (e.g., cyclotron) at or within close proximity to the site where the PET procedure will be conducted. The radionuclides may then be synthetically incorporated into the final PET radiopharmaceutical for subsequent patient administration.

The following requirements address the compounding of PET radiopharmaceuticals for human use (see also [Automated Radiochemical Synthesis Apparatus](#) (1015)).

Control of Components, Materials, and Supplies

The following activities are to be established and performed. A designated person shall be responsible for ensuring that these activities are carried out and completed properly.

(1) Establish written specifications for

- the identity, purity, and quality of components (including ingredients, reagents, target solutions, and gases); the identity and quality of containers and closures, and other materials (e.g., transfer lines, purification devices, membrane filters) that come into contact with the final PET radiopharmaceutical; and the identity, purity, and quality of analytical supplies (e.g., solvents, chromatography columns, and reference materials), sterility test media, endotoxin test reagents, and other supplies intended for use in PET radiopharmaceutical quality control procedures; and
- the appropriate storage (i.e., based on heat, light, and humidity considerations) of components, containers and closures, materials and supplies used for the compounding of PET radiopharmaceuticals.

(2) Log-in each lot of shipments of components, containers and closures, materials, and supplies used for the compounding of PET radiopharmaceuticals, and record the date of receipt, quantity received, manufacturer, lot number, and expiration date. If no expiration date is designated by the manufacturer, an expiration date is to be assigned to the component, material, or supply based on knowledge of its physical and chemical properties and prior experience with its use. For organic substrates, reactants, and reagent materials that are potentially susceptible to degradation or to a change in composition, the expiration date is based on the component's documented evidence of stability.

(3) Determine that each batch of components, containers and closures, materials, and supplies used for the compounding of PET radiopharmaceuticals are in compliance with

Established written specifications. A reliable manufacturer is routinely used as the source of a given product. Certification of compliance with the specifications for containers, closures, and materials marketed commercially for the intended purpose(s) may be accomplished by inspection of the product labeling and/or inspection of the certificate of analysis provided by the manufacturer. Certification of compliance with the specifications for other components and materials used in the compounding of PET radiopharmaceuticals may be accomplished by inspection of the certificate of analysis provided by the manufacturer. The identities of each lot of components, containers and closures, and materials used in the compounding of PET radiopharmaceuticals are to be verified by defined procedures, tests, and/or documented certificates of analysis, as appropriate.

(4) Store components, containers and closures, materials, and supplies used for the compounding of PET radiopharmaceuticals in a controlled access area according to established storage conditions.

#### Compounding Procedure Verification

The following activities are to be established or performed. A designated, qualified, and trained person shall be responsible for ensuring that these activities are carried out and properly completed by qualified and trained personnel.

(1) Written acceptance criteria for the identity, purity, and quality of each PET radiopharmaceutical being compounded. If a USP monograph exists for a particular PET, then these standards are the minimum acceptance criteria (see Official and Official Articles under the General Notices and Requirements).

(2) Written and verified procedures for the compounding of each PET radiopharmaceutical that

- incorporate, for each PET radiopharmaceutical intended for parenteral administration, sterile membrane filtration (0.22 µm);
- incorporate, for each PET radiopharmaceutical intended for inhalation, particulate filtration (0.45 µm); and
- are routinely updated and verified as changes in the compounding procedures are implemented or are reviewed and verified at a minimum of once a year to ensure that they are current. A master file of written compounding procedures currently used for each PET radiopharmaceutical is to be maintained within the PET facility. Copies of outdated compounding procedures shall also be retained, separate from the master file, for review purposes.

(3) Appropriate controls over computer and related automated equipment to ensure that changes in compounding software are instituted only by authorized personnel, that such changes are documented and verified, and that only current versions of the software are available and used in PET radiopharmaceutical compounding procedures. A diskette copy and printout of current computer software programs used in the compounding of each PET radiopharmaceutical is to be maintained within a master file located in the PET facility. Copies of outdated computer software programs shall also be retained, separate from the master file, for review purposes.

(4) Verification studies to ensure that the written compounding procedures, computer software program, equipment, and facilities result in a PET radiopharmaceutical that meets established acceptance criteria. Such verification studies must

- include documented evaluations of the radiochemical identity and purity, radionuclidic identity and purity, specific activity, sterility (for parenteral agents), bacterial endotoxins (for parenteral agents), pH, osmolarity (for parenteral agents), if appropriate, appearance, stereochemical purity (for applicable compounds), potential organic volatile impurities, other toxic chemicals that may have been used during the synthesis or purification procedure, effective concentration of a stabilizer (if any), chemical purity of the PET radiopharmaceutical [note—Evaluations for chemical purity must include analyses for the presence of starting materials, known intermediates, by-products, and known degradation products], and equivalency of initial and final sub-batches (for PET radiopharmaceuticals with radionuclides having a  $T\frac{1}{2} < 20.0$  minutes). For purposes of this chapter, "sub-batch" is defined as a quantity of PET drug product having uniform character and quality, within specified limits, that is produced during one succession of multiple irradiations, using a given synthesis and/or purification operation; and
- be signed, and dated, and retained as an indication that the compounding procedures, equipment, and facilities have resulted in a PET radiopharmaceutical that meets established acceptance criteria.

Whenever there is a change in the compounding procedures, computer software program, or component specifications that has the potential to alter the identity, quality, or purity of the drug product, verification procedures and studies must be conducted. Verification studies on a minimum of three consecutive batches, which show that the product meets acceptance criteria, are to be performed prior to the approval, for human use, of new or revised compounding procedures for a given PET radiopharmaceutical. For routine verified processes that are being used with consistent success, a minimum of one verification study that shows the product meets acceptance criteria must be conducted on an annual basis.

#### Stability Testing and Expiration Dating

Written specifications for the expiration dating and storage conditions of each PET radiopharmaceutical are to be established based on the results of stability testing and specific activity considerations. The stability test specimen must be taken from the product stored in the container and closure system specified for storing the product. The PET radiopharmaceutical must meet all acceptance criteria at expiry. Whenever there is a change in the compounding procedures, computer software program, or component specifications that has the potential to affect the stability of the drug product, stability testing must be conducted.

#### PET Radiopharmaceutical Compounding for Human Use

The following are to be performed according to established written procedures and documented. A designated, qualified, and trained person shall be responsible for ensuring that these activities are carried out and completed properly by qualified and trained personnel.

(1) Inspect the compounding and dispensing area and all equipment for cleanliness and suitability immediately before use. Before initiating compounding and dispensing activities, extraneous materials and labels must be removed from involved areas and equipment. For PET radiopharmaceuticals intended for parenteral administration, all manipulations of components, containers and closures, and materials distal to sterile membrane filtration must be performed using an appropriate aseptic technique in an appropriately controlled environment.

(2) Ensure the correct identity, quantity, and suitability of components, containers and closures, and other materials used in compounding the PET radiopharmaceutical.

(3) Label all subdivided components used in the compounding procedure for identity and traceability.

(4) Label the final PET radiopharmaceutical container or dispensing-administration assembly prior to initiating the compounding procedure. The following information must appear on the label or labeling attached to the final container or dispensing-administration assembly: the identity of the PET radiopharmaceutical, and added substances (e.g., stabilizers and preservatives), an assigned batch or lot number, and the required warning (e.g., radioactive) statements or symbols. The final PET radiopharmaceutical shall also be labeled to include the total radioactivity and radioactive concentration at the stated time of calibration, the expiration time and date, and any required or applicable warning statements (e.g., "Caution- Radioactive Material", "Do not use if cloudy or contains particulate matter") and/or the radioactivity symbol.

(5) Compound the PET radiopharmaceutical according to current, verified procedures. A written record must be maintained for each batch (i.e., the material produced during a single synthesis and purification) of the compounded PET radiopharmaceutical. This written record includes

- lot numbers, manufacturer identities, expiration dates, and quantities of all components, containers and closures, and materials used in the compounding procedure;
- a description of the individual compounding procedures to be followed;
- the initials of the responsible individual indicating that the compounding procedure for the batch is an accurate reproduction of the current, verified compounding procedure;
- the initials of the responsible individual indicating that critical steps and processes in the compounding procedure were completed [note—Critical steps in automated compounding processes shall be monitored through direct observation (if possible, considering visual or radiation exposure constraints) or via computer or other feedback mechanisms];
- documentation of the investigation of any unplanned deviations in, or unexpected results of, verified compounding procedures or processes, including documentation of the outcome of the investigation;
- the percent yield calculated on the basis of the known or expected decay-corrected amount of the starting radionuclide that is synthetically incorporated into the final radiopharmaceutical;

- raw analytical data on each batch of compounded PET radiopharmaceutical; and
- the date and the signature of the individual assuming overall responsibility for, and adherence to, the verified compounding procedure.

#### Quality Control

The following are to be performed according to established, written procedures and documented. A designated, qualified, and trained person shall be responsible for ensuring that these activities are carried out and completed properly by qualified and trained personnel.

(1) Establish, in writing, the quality control tests to be performed on individual batches of the PET radiopharmaceutical, the analytical procedures, and the corresponding acceptance criteria.

- For PET radiopharmaceuticals labeled with a nuclide having a  $T_{1/2} \geq 20.0$  minutes, the following quality control procedures are to be performed on each batch (i.e., the material produced during a single synthesis and purification operation) prior to release: measurement of the pH of parenteral and oral dosage forms; visual inspection of parenteral and oral dosage forms; determination of the radiochemical purity and identity of all dosage forms; determination of the radionuclidic identity of all dosage forms; and assessment of the specific activity of PET radiopharmaceuticals with mass-dependent localization or toxicity concerns; and evidence of compliance with the established acceptance criteria for residual solvents and other toxic chemicals used during the synthesis or purification procedures.
- For PET radiopharmaceuticals labeled with a nuclide having a  $T_{1/2} < 20.0$  minutes, a batch is defined as all related sub-batches of the PET radiopharmaceutical compounded during a given day. The following quality control procedures are to be performed on an initial quality control sub-batch of each such PET radiopharmaceutical prior to release for human use of subsequent sub-batches: measurement of the pH of parenteral and oral dosage forms; visual inspection of parenteral and oral dosage forms; determination of the radiochemical purity and identity of all dosage forms; determination of radionuclidic identity of all dosage forms; and assessment of the specific activity of PET radiopharmaceuticals with mass-dependent localization or toxicity concerns; and evidence of compliance with the established acceptance criteria for residual solvents and other toxic chemicals used or produced during the synthesis or purification procedures.
- For each batch of PET radiopharmaceutical intended for parenteral administration, perform a membrane filter integrity test immediately after completion of product filtration. This post-filtration integrity test is to be completed prior to release of the batch for human use, except in the case of 15O water, where it may be necessary to release the batch prior to completion of the post-filtration integrity test. In this case, the test is completed as soon as possible after release of the batch.
- For PET radiopharmaceuticals intended for parenteral administration, perform an in-process 20-minute endotoxin "limit test" (i.e., incorporating positive controls in the range of 5 EU per mL to 175 EUV, where V is the maximum volume of injection) on each batch ( $T_{1/2} \geq 20.0$  minutes) or quality control sub-batch ( $T_{1/2} < 20.0$  minutes) of the radiopharmaceutical prior to release, for human use, of the batch or subsequent sub-batches.
- For PET radiopharmaceuticals intended for parenteral administration, a standard 60-minute bacterial endotoxin test must be performed on each batch ( $T_{1/2} \geq 20.0$  minutes) or quality control sub-batch ( $T_{1/2} < 20.0$  minutes) of the radiopharmaceutical. Endotoxin testing may also be performed using other recognized procedures (see [Bacterial Endotoxins Test](#) (85)). Regardless of which test is utilized, an assessment of the bacterial endotoxins should be performed prior to release of each batch ( $T_{1/2} \geq 20.0$  minutes) or quality control sub-batch ( $T_{1/2} < 20.0$  minutes) of the radiopharmaceutical before release for human use of the batch or subsequent sub-batches.
- Sterility tests for each PET radiopharmaceutical intended for parenteral administration are performed on each batch ( $T_{1/2} \geq 20.0$  minutes) or quality control sub-batch ( $T_{1/2} < 20.0$  minutes). Sterility tests are also performed following the replacement of system components. Sterility tests are initiated within 24 hours of sterile filtration. Product samples are tested individually and are not pooled.

(2) Establish written procedures for the performance of quality control tests on batches of PET radiopharmaceuticals intended for human use.

(3) Conduct verification testing of equipment and procedures used for the quality control testing of PET radiopharmaceuticals. Using internal or external standards, the correct operation of analytical equipment, such as gas chromatography or high-performance liquid chromatography (see System Suitability under [Chromatography](#) (621)) must be confirmed upon initial installation or upon major repair. Correct operation of analytical equipment must also be checked (i.e., a system suitability test must be performed) on a scheduled basis, and maintenance must be performed according to appropriate, written, scheduled procedures. Dose calibrators used in measuring the bulk radioactivity and the radioactivity of dispensed dosages of PET radiopharmaceuticals should be tested in accordance with applicable state regulations governing the medical use of radioactive materials.

(4) Perform quality control tests on batches of PET radiopharmaceuticals according to written procedures, and initial the results of such testing.

(5) Accept or reject the individual batch of the PET radiopharmaceutical based on the conformity of quality control test results with established acceptance criteria. If the individual batch of the PET radiopharmaceutical is acceptable, sign and date the batch.

(6) Investigate unacceptable quality control test results and document the outcome of such investigations.

#### Sterilization and Sterility Assurance

A complete system of process controls is required to assure sterility of PET radiopharmaceuticals. Sterilization activities for the following elements of the process are to be established, documented, and performed.

**Compounding Equipment and Components**— Equipment used to prepare PET radiopharmaceuticals must be properly cleaned and kept in sanitary condition. Equipment in contact with a PET drug solution may be processed to remove endotoxin and may be sterilized to eliminate bioburden. Prepared equipment is stored and protected to maintain cleanliness and, if necessary, sterility. It is recommended that components for PET products be obtained from qualified suppliers after verifying that the components meet specifications for sterile drug products. It is further recommended that sterile vials, syringes, transfer sets, and filters be obtained from commercial sources. If components are sterilized by the PET facility, the sterilization processes and asepsis of assembly components must be verified. Verification of sterilizer performance must be repeated periodically. Solutions for parenteral administration must be filter-sterilized and aseptically transferred to a sterile, nonpyrogenic, multiple-dose vial. Certain finished dosage forms of PET products may not be transferred to a vial and require special consideration.

**Environmental Controls**— The work area used for compounding the finished dosage form must be clean. The aseptic hood is protected from sources of microbial contamination and is located in an area where surrounding personnel traffic is controlled and limited. Appropriate clean laboratory clothing shall be worn when performing functions in the aseptic hood. Components, materials, and equipment are transferred to the aseptic area in protective wrapping or containers. Aseptic techniques are used whenever a sterile solution dosage form is handled. The containers, filter assembly, vent filters, and needles for the final dosage form must be sterile, disposable, and for single use only. After the filter and the product container are assembled, the sterility of this assembly must be preserved. If the sterility of any component is compromised, the component or set must be replaced. Before penetrating the finished product container, the septum of the product vial must be thoroughly swabbed with a disinfectant solution (i.e., freshly filtered or certified sterile 70% alcohol) and allowed to air-dry in the aseptic hood.

**Aseptic Hood**— Assemble the product filter and the container and closure system for the finished product in an aseptic hood. Sterile (aseptic) operations should be conducted within an aseptic workstation with an air cleanliness rating of class 100 (e.g., Laminar flow hood or isolator). The aseptic hood surfaces and equipment surfaces allow easy cleaning and disinfecting. Disinfectants are filtered or certified sterile with a manufacturer's certificate of analysis, and the hood's internal surfaces are cleaned and disinfected daily before use and after new equipment is brought in. Microbiological testing of the aseptic hood is performed periodically (e.g., weekly). This may be done by swab or contact plate for surfaces and settle plate or dynamic air sampler. Airborne, nonviable particle counting may be performed less frequently.

**Aseptic Technique**— All aseptic operations, including the assembly of sterile components, compounding, filtration, and manipulations of sterile solutions must be performed by operators qualified to work with aseptic techniques. Aseptic manipulations shall be performed using sterile items sealed in protective covering and opened within the aseptic hood. Any sterile equipment or component that is compromised by contact with a nonsterile surface must be replaced. Sterile components shall be transferred from the hood with closures in place. Aseptic operations are performed by operators wearing laboratory clothing appropriate for pharmaceutical compounding. Gloved hands are disinfected immediately before reaching into the aseptic hood.

Aseptic area operators are trained and evaluated periodically through observation as well as through microbiological tests. Aseptic techniques used to make sterile products are evaluated by simulations, in which a microbiological growth medium is substituted for the PET radiopharmaceutical solution. Process simulations include manipulations such as

connecting vents and filtration. Verification of the medium's growth promotion capability in the PET drug container is an essential control for process simulations. After completing the simulation process, the final product container is gently shaken to permit the medium to contact all surfaces, and the container and the medium are incubated (at 30° to 35°, 20° to 25°, or another suitable temperature) for 14 days with periodic examination for evidence of growth: the absence of growth in the containers is necessary for an acceptable test result. Simulations are performed in triplicate to qualify a new operator. Each operator repeats one simulation about once a year or any time procedures are changed.

**Qualification of the Filtration Process—** Sterilizing filtration is the final safeguard in removing microorganisms from solutions of PET radiopharmaceuticals. This critical procedure requires that microbial retention by membrane filters be demonstrated under specified conditions. Filters must not release particles or soluble compounds, bind product ingredients, or lose integrity during use. When the filters are prepared and sterilized by a commercial filter manufacturer, the filter manufacturer generally provides filtration conditions (i.e., pressure and flow rate); these conditions are not to be exceeded when preparing a PET drug product. For most aqueous solutions of near neutral pH, certification regarding microbial retention challenges to the selected filter may be obtained from the filter manufacturer. Certification of conformance to specifications must be examined and maintained for each filter lot.

Before using filters from a particular lot, a sample is tested for integrity to demonstrate that the membrane and housing have not lost the ability to retain microorganisms. The manufacturer's recommended method or an alternative method, if demonstrated to be acceptable, may be used.

The sterilizing membrane filter must also be tested for integrity after filtering the compounded PET radiopharmaceutical but before the product is released. An example of a simple test is the "Bubble Point" test, which uses a pressure gauge and a source of air pressure connected to the transfer set attached to the filter. The filter disk is placed in a beaker of water with the filter outlet below the water surface, and air pressure is applied gently to the nonsterile side of the filter assembly. The air pressure is increased until the validated bubble point is reached, at which point the pressure is maintained briefly to allow equilibration. Filter integrity is demonstrated to be acceptable in the absence of a steady stream of bubbles.

**Microbiological Testing of Finished Products—** PET radiopharmaceuticals for parenteral administration must be sterile and free of endotoxins, as demonstrated by sterility and endotoxin tests. Endotoxin tests are initiated promptly after compounding, and sterility tests are started no later than 24 hours after compounding. Each lot shall be assayed individually and not pooled with other lots. If a microbiological test fails, an investigation shall be undertaken to identify the cause, and corrections shall be undertaken. After a record of successful sterility tests is established for a particular PET drug, only the first lot prepared each day shall be subject to a sterility test using cultivation methods. However, when a different PET drug is made at the facility or a new lot of sterile components (for example, filter or final product container) is substituted, then the first daily lot of that PET drug is tested for sterility.

#### 831 REFRACTIVE INDEX

The refractive index (*n*) of a substance is the ratio of the velocity of light in air to the velocity of light in the substance. It is valuable in the identification of substances and the detection of impurities.

Although the standard temperature for Pharmacopeial measurements is 25°, many of the refractive index specifications in the individual monographs call for determining this value at 20°. The temperature should be carefully adjusted and maintained, since the refractive index varies significantly with temperature.

The values for refractive index given in this Pharmacopeia are for the D line of sodium (doublet at 589.0 nm and 589.6 nm). Most instruments available are designed for use with white light but are calibrated to give the refractive index in terms of the D line of sodium light.

The Abbé refractometer measures the range of refractive index for those Pharmacopeial materials for which such values are given. Other refractometers of equal or greater accuracy may be employed.

To achieve the theoretical accuracy of ±0.0001, it is necessary to calibrate the instrument against a standard provided by the manufacturer and to check frequently the temperature control and cleanliness of the instrument by determining the refractive index of distilled water, which is 1.3330 at 20° and 1.3325 at 25°.

USP32-NF27 Page 369

#### 841 SPECIFIC GRAVITY

Unless otherwise stated in the individual monograph, the specific gravity determination is applicable only to liquids, and, unless otherwise stated, is based on the ratio of the weight of a liquid in air at 25° to that of an equal volume of water at the same temperature. Where a temperature is specified in the individual monograph, the specific gravity is the ratio of the weight of the liquid in air at the specified temperature to that of an equal volume of water at the same temperature. When the substance is a solid at 25°, determine the specific gravity of the melted material at the temperature directed in the individual monograph, and refer to water at 25°.

Unless otherwise stated in the individual monograph, the density is defined as the mass of a unit volume of the substance at 25°, expressed in kilograms per cubic meter or grams per cubic centimeter (1 kg/m<sup>3</sup> = 10–3 g/cm<sup>3</sup>).

Unless otherwise directed in the individual monograph, use Method I.

#### METHOD I

**Procedure—** Select a scrupulously clean, dry pycnometer that previously has been calibrated by determining its weight and the weight of recently boiled water contained in it at 25°. Adjust the temperature of the liquid to about 20°, and fill the pycnometer with it. Adjust the temperature of the filled pycnometer to 25°, remove any excess liquid, and weigh. When the monograph specifies a temperature different from 25°, filled pycnometers must be brought to the temperature of the balance before they are weighed. Subtract the tare weight of the pycnometer from the filled weight.

The specific gravity of the liquid is the quotient obtained by dividing the weight of the liquid contained in the pycnometer by the weight of water contained in it, both determined at 25°, unless otherwise directed in the individual monograph.

#### METHOD II

The procedure includes the use of the Oscillating transducer density meter. The apparatus consists of the following:

- a U-shaped tube, usually of borosilicate glass, which contains the liquid to be examined;
- a magneto-electrical or piezo-electrical excitation system that causes the tube to oscillate as a cantilever oscillator at a characteristic frequency depending on the density of the

liquid to be examined;

- a means of measuring the oscillation period (T), which may be converted by the apparatus to give a direct reading of density or used to calculate density by using the constants A and B described below; and
- a means to measure and/or control the temperature of the oscillating transducer containing the liquid to be tested.

The oscillation period is a function of the spring constant (c) and the mass of the system:

$$T^2 = \left( \frac{M}{c} + \frac{\rho \times V}{c} \right) \times 4\pi^2$$

where  $\rho$  is the density of the liquid to be tested, M is the mass of the tube, and V is the volume of the filled tube.

Introduction of two constants A = c / (4π² × V) and B = M / V, leads to the classical equation for the oscillating transducer:

$$\rho = A \times T^2 - B$$

The specific gravity of the liquid is given by the formula:

$$\rho(L) / \rho(W)$$

where  $\rho(L)$  and  $\rho(W)$  are the densities of the liquid and water, respectively, both determined at 25°, unless otherwise directed in the individual monograph.

Calibration— The constants A and B are determined by operating the instrument with the U-tube filled with two different samples of known density (e.g., degassed water and air). Perform the control measurements daily, using degassed water: the results displayed for the control measurement using degassed water do not deviate from the reference value ( $\rho$  = 0.997043 g/cm³) by more than its specified error. Precision is a function of the repeatability and stability of the oscillator frequency. Density meters are able to achieve measurements with an error on the order of 1×10-3g/cm-3 to 1×10-5g/cm-3 and a repeatability of 1×10-4g/cm-3 to 1×10-6g/cm-3. For example, an instrument specified to ±1×10-4g/cm-3 must display 0.9970 ± 0.0001 g/cm-3 in order to be suitable for further measurement, otherwise a readjustment is necessary. Calibration with certified reference materials should be carried out regularly.

Procedure— Using the manufacturer's instructions, perform the measurements using the same procedure as for Calibration. If necessary, equilibrate the liquid to be examined at 25° before introduction into the tube to avoid the formation of bubbles and to reduce the time required for measurement. Factors affecting accuracy include the following:

- temperature uniformity throughout the tube,
- nonlinearity over a range of density,
- parasitic resonant effects, and
- viscosity, if the oscillating transducer density meters used do not provide automatic compensation of sample viscosity influence.

846 SPECIFIC SURFACE AREA

## INTRODUCTION

The specific surface area of a powder is determined by physical adsorption of a gas on the surface of the solid and by calculating the amount of adsorbate gas corresponding to a monomolecular layer on the surface. Physical adsorption results from relatively weak forces (van der Waals forces) between the adsorbate gas molecules and the adsorbent surface of the test powder. The determination is usually carried out at the temperature of liquid nitrogen. The amount of gas adsorbed can be measured by a volumetric or continuous flow procedure.

### BRUNAUER, EMMETT AND TELLER (BET) THEORY AND SPECIFIC SURFACE AREA DETERMINATION

#### Multipoint Measurement

The data are treated according to the Brunauer, Emmett and Teller (BET) adsorption isotherm equation:

$$\left[ \frac{1}{V_a \left( \frac{P_o}{P} - 1 \right)} \right] = \frac{C-1}{V_m C} \times \frac{P}{P_o} + \frac{1}{V_m C} \quad (1)$$

P = partial vapor pressure of adsorbate gas in equilibrium with the surface at 77.4 K (b.p. of liquid nitrogen), in Pa,

P<sub>o</sub> = saturated pressure of adsorbate gas, in Pa,

V<sub>a</sub> = volume of gas adsorbed at standard temperature and pressure (STP) [273.15 K and atmospheric pressure (1.013 × 10<sup>5</sup> Pa)], in mL,

V<sub>m</sub> = volume of gas adsorbed at STP to produce an apparent monolayer on the sample surface, in mL,

C = dimensionless constant that is related to the enthalpy of adsorption of the adsorbate gas on the powder sample.

A value of V<sub>a</sub> is measured at each of not less than three values of P/P<sub>o</sub>.

Then the BET value

1

$$\frac{1}{V_a \left( \frac{P_o}{P} - 1 \right)}$$

is plotted against  $P/P_o$ , according to equation (1). This plot should yield a straight line usually in the approximate relative pressure range 0.05 to 0.3. The data are considered acceptable if the correlation coefficient,  $r$ , of the linear regression is not less than 0.9975; that is,  $r^2$  is not less than 0.995. From the resulting linear plot, the slope, which is equal to  $(C - 1)/VmC$ , and the intercept, which is equal to  $1/VmC$ , are evaluated by linear regression analysis. From these values,  $Vm$  is calculated as  $1/(slope + intercept)$ , while  $C$  is calculated as  $(slope/intercept) + 1$ . From the value of  $Vm$  so determined, the specific surface area,  $S$ , in  $m^2 \cdot g^{-1}$ , is calculated by the equation:

$$S = \frac{Vm Na}{m \times 22400} \quad (2)$$

$N$  = Avogadro constant ( $6.023 \times 1023 \text{ mol}^{-1}$ ),

$a$  = effective cross-sectional area of one adsorbate molecule, in square meters (0.162 nm $^2$  for nitrogen and 0.195 nm $^2$  for krypton),

$m$  = mass of test powder, in g,

22400 = volume, in mL, occupied by one mole of the adsorbate gas at STP allowing for minor departures from the ideal.

A minimum of three data points is required. Additional measurements may be carried out especially when nonlinearity is obtained at a  $P/P_o$  value close to 0.3. Because nonlinearity is often obtained at a  $P/P_o$  value below 0.05, values in this region are not recommended. The test for linearity, the treatment of the data, and the calculation of the specific surface area of the sample are described above.

#### Single-Point Measurement

Normally, at least three measurements of  $Va$ , each at different values of  $P/P_o$ , are required for the determination of specific surface area by the dynamic flow gas adsorption technique (Method I) or by volumetric gas adsorption (Method II). However, under certain circumstances described below, it may be acceptable to determine the specific surface area of a powder from a single value of  $Va$  measured at a single value of  $P/P_o$  such as 0.300 (corresponding to 0.300 mole of nitrogen or 0.001038 mole fraction of krypton), using the following equation for calculating  $Vm$ :

$$Vm = V_a \left( 1 - \frac{P}{P_o} \right) \quad (3)$$

The specific surface area is then calculated from the value of  $Vm$  by equation (2) given above.

The single-point method may be employed directly for a series of powder samples of a given material for which the material constant  $C$  is much greater than unity. These circumstances may be verified by comparing values of specific surface area determined by the single-point method with that determined by the multipoint method for the series of powder samples. Close similarity between the single-point values and multipoint values suggests that  $1/C$  approaches zero.

The single-point method may be employed indirectly for a series of very similar powder samples of a given material for which the material constant  $C$  is not infinite but may be assumed to be invariant. Under these circumstances, the error associated with the single-point method can be reduced or eliminated by using the multipoint method to evaluate  $C$  for one of the samples of the series from the BET plot, from which  $C$  is calculated as  $(1 + \text{slope}/\text{intercept})$ . Then  $Vm$  is calculated from the single value of  $Va$  measured at a single value of  $P/P_o$ , by the equation:

$$Vm = V_a \left( \frac{P_o}{P} - 1 \right) \left[ \frac{1}{C} + \frac{C-1}{C} \times \left( \frac{P}{P_o} \right) \right] \quad (4)$$

The specific surface area is calculated from  $Vm$  by equation (2) given above.

#### EXPERIMENTAL TECHNIQUES

This section describes the methods to be used for the sample preparation, the dynamic flow gas adsorption technique (Method I) and the volumetric gas adsorption technique (Method II).

##### Sample Preparation

##### outgassing

Before the specific surface area of the sample can be determined, it is necessary to remove gases and vapors that may have become physically adsorbed onto the surface after manufacture and during treatment, handling, and storage. If outgassing is not achieved, the specific surface area may be reduced or may be variable because an intermediate area of the surface is covered with molecules of the previously adsorbed gases or vapors. The outgassing conditions are critical for obtaining the required precision and accuracy of specific surface area measurements on pharmaceuticals because of the sensitivity of the surface of the materials.

The outgassing conditions must be demonstrated to yield reproducible BET plots, a constant weight of test powder, and no detectable physical or chemical changes in the test powder.

The outgassing conditions defined by the temperature, pressure, and time are chosen so that the original surface of the solid is reproduced as closely as possible. Outgassing of many

Substances is often achieved by applying a vacuum by purging the sample in a flowing stream of a nonreactive, dry gas or by applying a desorption-adsorption cycling method. In either case, elevated temperatures are sometimes applied to increase the rate at which the contaminants leave the surface. Caution should be exercised when outgassing powder samples using elevated temperatures to avoid affecting the nature of the surface and the integrity of the sample.

If heating is employed, the recommended temperature and time of outgassing are as low as possible to achieve reproducible measurement of specific surface area in an acceptable time. For outgassing sensitive samples, other outgassing methods such as the desorption-adsorption cycling method may be employed.

#### adsorbate

The standard technique is the adsorption of nitrogen of analytical quality at liquid nitrogen temperature.

For powders of low specific surface area (< 0.2 m<sup>2</sup>g<sup>-1</sup>), the proportion adsorbed is low. In such cases, the use of krypton at the liquid nitrogen temperature is preferred because the low vapor pressure exerted by this gas greatly reduces error. The use of larger sample quantities, where feasible (equivalent to 1 m<sup>2</sup> or greater total surface area using nitrogen), may compensate for the errors in determining low surface areas.

All gases used must be free from moisture.

#### quantity of sample

A quantity of the test powder is accurately weighed such that the total surface of the sample is at least 1 m<sup>2</sup> when the adsorbate is nitrogen and 0.5 m<sup>2</sup> when the adsorbate is krypton.

Lower quantities of sample may be used after appropriate validation.

#### Measurements

Because the amount of gas adsorbed under a given pressure tends to increase when the temperature is decreased, adsorption measurements are usually made at a low temperature. Measurement is performed at 77.4 K, the boiling point of liquid nitrogen.

#### Method I: The Dynamic Flow Method

##### principle

In the dynamic flow method (see [Figure 1](#)), the recommended adsorbate gas is dry nitrogen or krypton, while helium is employed as a diluent gas, which is not adsorbed under the recommended conditions.

A minimum of three mixtures of the appropriate adsorbate gas with helium are required within the P/P<sub>0</sub> range 0.05 to 0.30.

The gas detector-integrator should provide a signal that is approximately proportional to the volume of the gas passing through it under defined conditions of temperature and pressure. For this purpose, a thermal conductivity detector with an electronic integrator is one among various suitable types. A minimum of three data points within the recommended range of 0.05 to 0.30 for P/P<sub>0</sub> is determined.

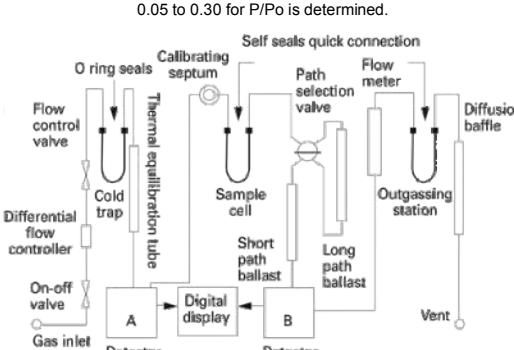

Fig. 1. Schematic diagram of the dynamic flow method apparatus.

#### procedure

A known mixture of the gases, usually nitrogen and helium, is passed through a thermal conductivity cell, through the sample again, through the thermal conductivity cell, and then to a recording potentiometer.

The sample cell is immersed in liquid nitrogen, and the sample adsorbs nitrogen from the mobile phase. This unbalances the thermal conductivity cell, and a pulse is generated on a recorder chart.

The sample is removed from the coolant; this gives a desorption peak equal in area and in the opposite direction to the adsorption peak. Because this is better defined than the adsorption peak, it is the one used for the determination.

To effect the calibration, a known quantity of adsorbate, sufficient to give a peak of similar magnitude to the desorption peak, is injected into the system, and the proportion of gas volume per unit peak area is obtained.

A mixture of nitrogen and helium is used for a single-point determination; and several such mixtures or premixing two streams of gas are used for a multipoint determination.

The calculation is the same as the volumetric method.

#### Method II: The Volumetric Method

##### principle

In the volumetric method (see [Figure 2](#)), the recommended adsorbate gas is nitrogen, which is admitted into the evacuated space above the previously outgassed powder sample to give a defined equilibrium pressure, P, of the gas. The use of a diluent gas, such as helium, is therefore unnecessary, although helium may be employed for other purposes, such as to measure the dead volume.

Because only pure adsorbate gas, instead of a gas mixture, is employed, interfering effects of thermal diffusion are avoided in this method.

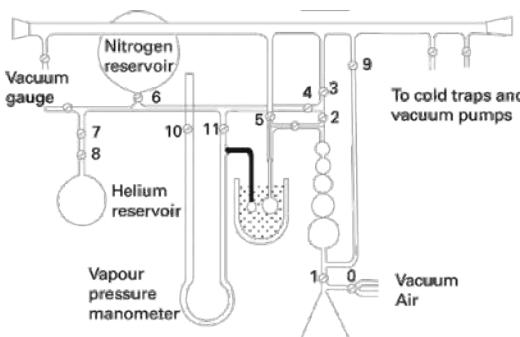

Fig. 2. Schematic diagram of the volumetric method apparatus.

## procedure

A small amount of dry nitrogen is admitted into the sample tube to prevent contamination of the clean surface, the sample tube is removed, a stopper is inserted, the tube is weighed, and the weight of the sample is calculated. Then the sample tube is attached to the volumetric apparatus. The sample is cautiously evacuated down to the specified pressure (e.g., between 2 Pa and 10 Pa). Alternately, some instruments are operated by evacuating to a defined rate of pressure change (e.g., less than 13 Pa/30 s) and by holding for a defined period of time before commencing the next step.

If the principle of operation of the instrument requires the determination of the dead volume in the sample tube, for example, by the admission of a nonadsorbed gas, such as helium, this procedure is carried out at this point, followed by evacuation of the sample. The determination of dead volume may be avoided using difference measurements: that is, by means of reference and sample tubes connected by a differential transducer. The adsorption of nitrogen gas is then measured as described below.

Raise a Dewar vessel containing liquid nitrogen at 77.4 K up to a defined point on the sample cell. Admit a sufficient volume of adsorbate gas to give the lowest desired relative pressure. Measure the volume adsorbed,  $V_a$ . For multipoint measurements, repeat the measurement of  $V_a$  at successively higher  $P/P_0$  values. When nitrogen is used as the adsorbate gas,  $P/P_0$  values of 0.10, 0.20, and 0.30 are often suitable.

## Reference Materials

Periodically verify the functioning of the apparatus using appropriate reference materials of known surface area that have a specific surface area similar to that of the sample to be examined.

## 851 SPECTROPHOTOMETRY AND LIGHT-SCATTERING

### ULTRAVIOLET, VISIBLE, INFRARED, ATOMIC ABSORPTION, FLUORESCENCE, TURBIDIMETRY, NEPHELOMETRY, AND RAMAN MEASUREMENT

Absorption spectrophotometry is the measurement of an interaction between electromagnetic radiation and the molecules, or atoms, of a chemical substance. Techniques frequently employed in pharmaceutical analysis include UV, visible, IR, and atomic absorption spectroscopy. Spectrophotometric measurement in the visible region was formerly referred to as colorimetry; however, it is more precise to use the term "colorimetry" only when considering human perception of color.

Fluorescence spectrophotometry is the measurement of the emission of light from a chemical substance while it is being exposed to UV, visible, or other electromagnetic radiation. In general, the light emitted by a fluorescent solution is of maximum intensity at a wavelength longer than that of the exciting radiation, usually by some 20 to 30 nm.

Light-Scattering involves measurement of the light scattered because of submicroscopic optical density inhomogeneities of solutions and is useful in the determination of weight-average molecular weights of polydisperse systems in the molecular weight range from 1000 to several hundred million. Two such techniques utilized in pharmaceutical analysis are turbidimetry and nephelometry.

Raman spectroscopy (inelastic light-scattering) is a light-scattering process in which the specimen under examination is irradiated with intense monochromatic light (usually laser light) and the light scattered from the specimen is analyzed for frequency shifts.

The wavelength range available for these measurements extends from the short wavelengths of the UV through the IR. For convenience of reference, this spectral range is roughly divided into the UV (190 to 380 nm), the visible (380 to 780 nm), the near-IR (780 to 3000 nm), and the IR (2.5 to 40  $\mu$ m or 4000 to 250  $\text{cm}^{-1}$ ).

### COMPARATIVE UTILITY OF SPECTRAL RANGES

For many pharmaceutical substances, measurements can be made in the UV and visible regions of the spectrum with greater accuracy and sensitivity than in the near-IR and IR. When solutions are observed in 1-cm cells, concentrations of about 10  $\mu$ g of the specimen per mL often will produce absorbances of 0.2 to 0.8 in the UV or the visible region. In the IR and near-IR, concentrations of 1 to 10 mg per mL and up to 100 mg per mL, respectively, may be needed to produce sufficient absorption; for these spectral ranges, cell lengths of from 0.01 mm to upwards of 3 mm are commonly used.

The UV and visible spectra of substances generally do not have a high degree of specificity. Nevertheless, they are highly suitable for quantitative assays, and for many substances they are useful as additional means of identification.

There has been increasing interest in the use of near-IR spectroscopy in pharmaceutical analysis, especially for rapid identification of large numbers of samples, and also for water determination.

The near-IR region is especially suitable for the determination of  $-\text{OH}$  and  $-\text{NH}$  groups, such as water in alcohol,  $-\text{OH}$  in the presence of amines, alcohols in hydrocarbons, and primary and secondary amines in the presence of tertiary amines.

The IR spectrum is unique for any given chemical compound with the exception of optical isomers, which have identical spectra. However, polymorphism may occasionally be responsible for a difference in the IR spectrum of a given compound in the solid state. Frequently, small differences in structure result in significant differences in the spectra. Because of the large number of maxima in an IR absorption spectrum, it is sometimes possible to quantitatively measure the individual components of a mixture of known qualitative composition without prior separation.

The Raman spectrum and the IR spectrum provide similar data, although the intensities of the spectra are governed by different molecular properties. Raman and IR spectroscopy

...hibit different relative sensitivities for different functional groups, e.g., Raman spectroscopy is particularly sensitive to C–S and C–C multiple bonds, and some aromatic compounds are more easily identified by means of their Raman spectra. Water has a highly intense IR absorption spectrum, but a particularly weak Raman spectrum. Therefore, water has only limited IR "windows" that can be used to examine aqueous solutes, while its Raman spectrum is almost completely transparent and useful for solute identification. The two major limitations of Raman spectroscopy are that the minimum detectable concentration of specimen is typically 10-1 M to 10-2 M and that the impurities in many substances fluoresce and interfere with the detection of the Raman scattered signal.

Optical reflectance measurements provide spectral information similar to that obtained by transmission measurements. Since reflectance measurements probe only the surface composition of the specimen, difficulties associated with the optical thickness and the light-scattering properties of the substance are eliminated. Thus, reflectance measurements are frequently more simple to perform on intensely absorbing materials. A particularly common technique used for IR reflectance measurements is termed attenuated total reflectance (ATR), also known as multiple internal reflectance (MIR). In the ATR technique, the beam of the IR spectrometer is passed through an appropriate IR window material (e.g., KRS-5, a TiBr-TlI eutectic mixture), which is cut at such an angle that the IR beam enters the first (front) surface of the window, but is totally reflected when it impinges on the second (back) surface (i.e., the angle of incidence of the radiation upon the second surface of the window exceeds the critical angle for that material). By appropriate window construction, it is possible to have many internal reflections of the IR beam before it is transmitted out of the window. If a specimen is placed in close contact with the window along the sides that totally reflect the IR beam, the intensity of reflected radiation is reduced at each wavelength (frequency) that the specimen absorbs. Thus, the ATR technique provides a reflectance spectrum that has been increased in intensity, when compared to a simple reflectance measurement, by the number of times that the IR beam is reflected within the window. The ATR technique provides excellent sensitivity, but it yields poor reproducibility, and is not a reliable quantitative technique unless an internal standard is intimately mixed with each test specimen.

Fluorescence spectrophotometry is often more sensitive than absorption spectrophotometry. In absorption measurements, the specimen transmittance is compared to that of a blank; and at low concentrations, both solutions give high signals. Conversely, in fluorescence spectrophotometry, the solvent blank has low rather than high output, so that the background radiation that may interfere with determinations at low concentrations is much less. Whereas few compounds can be determined conveniently at concentrations below 10-5 M by light absorption, it is not unusual to employ concentrations of 10-7 M to 10-8 M in fluorescence spectrophotometry.

#### THEORY AND TERMS

The power of a radiant beam decreases in relation to the distance that it travels through an absorbing medium. It also decreases in relation to the concentration of absorbing molecules or ions encountered in that medium. These two factors determine the proportion of the total incident energy that emerge. The decrease in power of monochromatic radiation passing through a homogeneous absorbing medium is stated quantitatively by Beer's law,  $\log(1/T) = A = abc$ , in which the terms are as defined below.

Absorbance [Symbol: A]—The logarithm, to the base 10, of the reciprocal of the transmittance (T). [note—Descriptive terms used formerly include optical density, absorbancy, and extinction.]

Absorptivity [Symbol: a]—The quotient of the absorbance (A) divided by the product of the concentration of the substance (c), expressed in g per L, and the absorption path length (b) in cm. [note—It is not to be confused with absorbancy index; specific extinction; or extinction coefficient.]

Molar Absorptivity [Symbol: ε]—The quotient of the absorbance (A) divided by the product of the concentration, expressed in moles per L, of the substance and the absorption path length in cm. It is also the product of the absorptivity (a) and the molecular weight of the substance. [note—Terms formerly used include molar absorbancy index; molar extinction coefficient; and molar absorption coefficient.]

For most systems used in absorption spectrophotometry, the absorptivity of a substance is a constant independent of the intensity of the incident radiation, the internal cell length, and the concentration, with the result that concentration may be determined photometrically.

Beer's law gives no indication of the effect of temperature, wavelength, or the type of solvent. For most analytical work the effects of normal variation in temperature are negligible.

Deviations from Beer's law may be caused by either chemical or instrumental variables. Apparent failure of Beer's law may result from a concentration change in solute molecules because of association between solute molecules or between solute and solvent molecules, or dissociation or ionization. Other deviations might be caused by instrumental effects such as polychromatic radiation, slit-width effects, or stray light.

Even at a fixed temperature in a given solvent, the absorptivity may not be truly constant. However, in the case of specimens having only one absorbing component, it is not necessary that the absorbing system conform to Beer's law for use in quantitative analysis. The concentration of an unknown may be found by comparison with an experimentally determined standard curve.

Although, in the strictest sense, Beer's law does not hold in atomic absorption spectrophotometry because of the lack of quantitative properties of the cell length and the concentration, the absorption processes taking place in the flame under conditions of reproducible aspiration do follow the Beer relationship in principle. Specifically, the negative log of the transmittance, or the absorbance, is directly proportional to the absorption coefficient, and, consequently, is proportional to the number of absorbing atoms. On this basis, calibration curves may be constructed to permit evaluation of unknown absorption values in terms of concentration of the element in solution.

Absorption Spectrum—A graphic representation of absorbance, or any function of absorbance, plotted against wavelength or function of wavelength.

Transmittance [Symbol: T]—The quotient of the radiant power transmitted by a specimen divided by the radiant power incident upon the specimen. [note—Terms formerly used include transmittancy and transmission.]

Fluorescence Intensity [Symbol: I]—An empirical expression of fluorescence activity, commonly given in terms of arbitrary units proportional to detector response. The fluorescence emission spectrum is a graphical presentation of the spectral distribution of radiation emitted by an activated substance, showing intensity of emitted radiation as ordinate, and wavelength as abscissa. The fluorescence excitation spectrum is a graphical presentation of the activation spectrum, showing intensity of radiation emitted by an activated substance as ordinate, and wavelength of the incident (activating) radiation as abscissa. As in absorption spectrophotometry, the important regions of the electromagnetic spectrum encompassed by the fluorescence of organic compounds are the UV, visible, and near-IR, i.e., the region from 250 to 800 nm. After a molecule has absorbed radiation, the energy can be lost as heat or released in the form of radiation of the same or longer wavelength as the absorbed radiation. Both absorption and emission of radiation are due to the transitions of electrons between different energy levels, or orbitals, of the molecule. There is a time delay between the absorption and emission of light; this interval, the duration of the excited state, has been measured to be about 10-9 second to 10-8 second for most organic fluorescent solutions. The short lifetime of fluorescence distinguishes this type of luminescence from phosphorescence, which is a long-lived afterglow having a lifetime of 10-3 second up to several minutes.

Turbidance [Symbol: S]—The light-scattering effect of suspended particles. The amount of suspended matter may be measured by observation of either the transmitted light (turbidimetry) or the scattered light (nephelometry).

Turbidity [Symbol: T]—In light-scattering measurements, the turbidity is the measure of the decrease in incident beam intensity per unit length of a given suspension.

Raman Scattering Activity—The molecular property (in units of  $\text{cm}^4 \text{ per g}$ ) governing the intensity of an observed Raman band for a randomly oriented specimen. The scattering activity is determined from the derivative of the molecular polarizability with respect to the molecular motion giving rise to the Raman shifted band. In general, the Raman band intensity is linearly proportional to the concentration of the analyte.

#### USE OF REFERENCE STANDARDS

With few exceptions, the Pharmacopeial spectrophotometric tests and assays call for comparison against a USP Reference Standard. This is to ensure measurement under conditions identical for the test specimen and the reference substance. These conditions include wavelength setting, slit-width adjustment, cell placement and correction, and transmittance levels. It should be noted that cells exhibiting identical transmittance at a given wavelength may differ considerably in transmittance at other wavelengths. Appropriate cell corrections should be established and used where required.

The expressions, "similar preparation" and "similar solution," as used in tests and assays involving spectrophotometry, indicate that the reference specimen, generally a USP Reference Standard, is to be prepared and observed in a manner identical for all practical purposes to that used for the test specimen. Usually in making up the solution of the

Specified Reference Standard, a solution of about (i.e., within 10%) the desired concentration is prepared and the absorptivity is calculated on the basis of the exact amount weighed out; if a previously dried specimen of the Reference Standard has not been used, the absorptivity is calculated on the anhydrous basis.

The expressions, "concomitantly determine" and "concomitantly measured," as used in tests and assays involving spectrophotometry, indicate that the absorbances of both the solution containing the test specimen and the solution containing the reference specimen, relative to the specified test blank, are to be measured in immediate succession.

#### APPARATUS

Many types of spectrophotometers are available. Fundamentally, most types, except those used for IR spectrophotometry, provide for passing essentially monochromatic radiant energy through a specimen in suitable form, and measuring the intensity of the fraction that is transmitted. Fourier transform IR spectrophotometers use an interferometric technique whereby polychromatic radiation passes through the analyte and onto a detector on an intensity and time basis. UV, visible, and dispersive IR spectrophotometers comprise an energy source, a dispersing device (e.g., a prism or grating), slits for selecting the wavelength band, a cell or holder for the test specimen, a detector of radiant energy, and associated amplifiers and measuring devices. In diode array spectrophotometers, the energy from the source is passed through the test specimen and then dispersed via a grating onto several hundred light-sensitive diodes, each of which in turn develops a signal proportional to the number of photons at its small wavelength interval; these signals then may be computed at rapid chosen intervals to represent a complete spectrum. Fourier transform IR systems utilize an interferometer instead of a dispersing device and a digital computer to process the spectral data. Some instruments are manually operated, whereas others are equipped for automatic and continuous recording. Instruments that are interfaced to a digital computer have the capabilities also of co-adding and storing spectra, performing spectral comparisons, and performing difference spectroscopy (accomplished with the use of a digital absorbance subtraction method).

Instruments are available for use in the visible; in the visible and UV; in the visible, UV, and near-IR; and in the IR regions of the spectrum. Choice of the type of spectrophotometric analysis and of the instrument to be used depends upon factors such as the composition and amount of available test specimen, the degree of accuracy, sensitivity, and selectivity desired, and the manner in which the specimen is handled.

The apparatus used in atomic absorption spectrophotometry has several unique features. For each element to be determined, a specific source that emits the spectral line to be absorbed should be selected. The source is usually a hollow-cathode lamp, the cathode of which is designed to emit the desired radiation when excited. Since the radiation to be absorbed by the test specimen element is usually of the same wavelength as that of its emission line, the element in the hollow-cathode lamp is the same as the element to be determined. The apparatus is equipped with an aspirator for introducing the test specimen into a flame, which is usually provided by air-acetylene, air-hydrogen, or, for refractory cases, nitrous oxide-acetylene. The flame, in effect, is a heated specimen chamber. A detector is used to read the signal from the chamber. Interfering radiation produced by the flame during combustion may be negated by the use of a chopped source lamp signal of a definite frequency. The detector should be tuned to this alternating current frequency so that the direct current signal arising from the flame is ignored. The detecting system, therefore, reads only the change in signal from the hollow-cathode source, which is directly proportional to the number of atoms to be determined in the test specimen. For Pharmacopeial purposes, apparatus that provides the readings directly in absorbance units is usually required.

However, instruments providing readings in percent transmission, percent absorption, or concentration may be used if the calculation formulas provided in the individual monographs are revised as necessary to yield the required quantitative results. Percent absorption or percent transmittance may be converted to absorbance, A, by the following two equations:

$$A = 2 - \log_{10} (100 - \% \text{ absorption})$$

or:

$$A = 2 - \log_{10} (\% \text{ transmittance})$$

Depending upon the type of apparatus used, the readout device may be a meter, digital counter, recorder, or printer. Both single-beam and double-beam instruments are commercially available, and either type is suitable.

Measurement of fluorescence intensity can be made with a simple filter fluorometer. Such an instrument consists of a radiation source, a primary filter, a specimen chamber, a secondary filter, and a fluorescence detection system. In most such fluorometers, the detector is placed on an axis at 90° from that of the exciting beam. This right-angle geometry permits the exciting radiation to pass through the test specimen and not contaminate the output signal received by the fluorescence detector. However, the detector unavoidably receives some of the exciting radiation as a result of the inherent scattering properties of the solutions themselves, or if dust or other solids are present. Filters are used to eliminate this residual scatter. The primary filter selects short-wavelength radiation capable of exciting the test specimen, while the secondary filter is normally a sharp cut-off filter that allows the longer-wavelength fluorescence to be transmitted but blocks the scattered excitation.

Most fluorometers use photomultiplier tubes as detectors, many types of which are available, each having special characteristics with respect to spectral region of maximum sensitivity, gain, and electrical noise. The photocurrent is amplified and read out on a meter or recorder.

A spectrofluorometer differs from a filter fluorometer in that filters are replaced by monochromators, of either the prism or the grating type. For analytical purposes, the spectrofluorometer is superior to the filter fluorometer in wavelength selectivity, flexibility, and convenience, in the same way in which a spectrophotometer is superior to a filter photometer.

Many radiation sources are available. Mercury lamps are relatively stable and emit energy mainly at discrete wavelengths. Tungsten lamps provide an energy continuum in the visible region. The high-pressure xenon arc lamp is often used in spectrofluorometers because it is a high-intensity source that emits an energy continuum extending from the UV into the IR.

In spectrofluorometers, the monochromators are equipped with slits. A narrow slit provides high resolution and spectral purity, while a large slit sacrifices these for high sensitivity. Choice of slit size is determined by the separation between exciting and emitting wavelengths as well as the degree of sensitivity needed.

Specimen cells used in fluorescence measurements may be round tubes or rectangular cells similar to those used in absorption spectrophotometry, except that they are polished on all four vertical sides. A convenient test specimen size is 2 to 3 mL, but some instruments can be fitted with small cells holding 100 to 300  $\mu$ L, or with a capillary holder requiring an even smaller amount of specimen.

Light-scattering instruments are available and consist in general of a mercury lamp, with filters for the strong green or blue lines, a shutter, a set of neutral filters with known transmittance, and a sensitive photomultiplier to be mounted on an arm that can be rotated around the solution cell and set at any angle from -135° to 0° to +135° by a dial outside the light-tight housing. Solution cells are of various shapes, such as square for measuring 90° scattering; semioctagonal for 45°, 90°, and 135° scattering; and cylindrical for scattering at all angles. Since the determination of molecular weight requires a precise measure of the difference in refractive index between the solution and solvent,  $[(n - n_0)/c]$ , a second instrument, a differential refractometer, is needed to measure this small difference.

Raman spectrometers include the following major components: a source of intense monochromatic radiation (invariably a laser); optics to collect the light scattered by the test specimen; a (double) monochromator to disperse the scattered light and reject the intense incident frequency; and a suitable light-detection and amplification system. Raman measurement is simple in that most specimens are examined directly in melting-point capillaries. Because the laser source can be focused sharply, only a few microliters of the specimen is required.

#### PROCEDURE

##### Absorption Spectrophotometry

Detailed instructions for operating spectrophotometers are supplied by the manufacturers. To achieve significant and valid results, the operator of a spectrophotometer should be aware of its limitations and of potential sources of error and variation. The instruction manual should be followed closely on such matters as care, cleaning, and calibration of the instrument, and techniques of handling absorption cells, as well as instructions for operation. The following points require special emphasis.

Check the instrument for accuracy of calibration. Where a continuous source of radiant energy is used, attention should be paid to both the wavelength and photometric scales; where a spectral line source is used, only the photometric scale need be checked. A number of sources of radiant energy have spectral lines of suitable intensity, adequately spaced throughout the spectral range selected. The best single source of UV and visible calibration spectra is the quartz-mercury arc, of which the lines at 253.7, 302.25, 313.16, 334.15,

48, 404.66, and 435.83 nm may be used. The glass-mercury arc is equally useful above 300 nm. The 486.13-nm and 656.28-nm lines of a hydrogen discharge lamp may be used also. The wavelength scale may be calibrated also by means of suitable glass filters, which have useful absorption bands through the visible and UV regions. Standard glasses containing didymium (a mixture of praseodymium and neodymium) have been used widely, although glasses containing holmium were found to be superior. Standard holmium oxide solution has superseded the use of holmium glass.<sup>1</sup> The wavelength scales of near-IR and IR spectrophotometers are readily checked by the use of absorption bands provided by polystyrene films, carbon dioxide, water vapor, or ammonia gas.

For checking the photometric scale, a number of standard inorganic glass filters as well as standard solutions of known transmittances such as potassium dichromate are available.<sup>2</sup>

Quantitative absorbance measurements usually are made on solutions of the substance in liquid-holding cells. Since both the solvent and the cell window absorb light, compensation must be made for their contribution to the measured absorbance. Matched cells are available commercially for UV and visible spectrophotometry for which no cell correction is necessary. In IR spectrophotometry, however, corrections for cell differences usually must be made. In such cases, pairs of cells are filled with the selected solvent and the difference in their absorbances at the chosen wavelength is determined. The cell exhibiting the greater absorbance is used for the solution of the test specimen and the measured absorbance is corrected by subtraction of the cell difference.

With the use of a computerized Fourier transform IR system, this correction need not be made, since the same cell can be used for both the solvent blank and the test solution. However, it must be ascertained that the transmission properties of the cell are constant.

Comparisons of a test specimen with a Reference Standard are best made at a peak of spectral absorption for the compound concerned. Assays prescribing spectrophotometry give the commonly accepted wavelength for peak spectral absorption of the substance in question. It is known that different spectrophotometers may show minor variation in the apparent wavelength of this peak. Good practice demands that comparisons be made at the wavelength at which peak absorption occurs. Should this differ by more than  $\pm 1$  nm from the wavelength specified in the individual monograph, recalibration of the instrument may be indicated.

#### test preparation

For determinations utilizing UV or visible spectrophotometry, the specimen generally is dissolved in a solvent. Unless otherwise directed in the monograph, determinations are made at room temperature using a path length of 1 cm. Many solvents are suitable for these ranges, including water, alcohols, chloroform, lower hydrocarbons, ethers, and dilute solutions of strong acids and alkalies. Precautions should be taken to utilize solvents free from contaminants absorbing in the spectral region being used. It is usually advisable to use water-free methanol or alcohol, or alcohol denatured by the addition of methanol but not containing benzene or other interfering impurities, as the solvent. Solvents of special spectrophotometric quality, guaranteed to be free from contaminants, are available commercially from several sources. Some other analytical reagent-grade organic solvents may contain traces of impurities that absorb strongly in the UV region. New lots of these solvents should be checked for their transparency, and care should be taken to use the same lot of solvent for preparation of the test solution and the standard solution and for the blank.

No solvent in appreciable thickness is completely transparent throughout the near-IR and IR spectrum. Carbon tetrachloride (up to 5 mm in thickness) is practically transparent to 6  $\mu$ m (1666  $\text{cm}^{-1}$ ). Carbon disulfide (1 mm in thickness) is suitable as a solvent to 40  $\mu$ m (250  $\text{cm}^{-1}$ ) with the exception of the 4.2- $\mu$ m to 5.0- $\mu$ m (2381- $\text{cm}^{-1}$  to 2000- $\text{cm}^{-1}$ ) and the 5.5- $\mu$ m to 7.5- $\mu$ m (1819- $\text{cm}^{-1}$  to 1333- $\text{cm}^{-1}$ ) regions, where it has strong absorption. Other solvents have relatively narrow regions of transparency. For IR spectrophotometry, an additional qualification for a suitable solvent is that it must not affect the material, usually sodium chloride, of which the cell is made. The test specimen may also be prepared by dispersing the finely ground solid specimen in mineral oil or by mixing it intimately with previously dried alkali halide salt (usually potassium bromide). Mixtures with alkali halide salts may be examined directly or as transparent disks or pellets obtained by pressing the mixture in a die. Typical drying conditions for potassium bromide are 105° in vacuum for 12 hours, although grades are commercially available that require no drying. Infrared microscopy or a mineral oil dispersion is preferable where disproportionation between the alkali halide and the test specimen is encountered. For suitable materials the test specimen may be prepared neat as a thin sample for IR microscopy or suspended neat as a thin film for mineral oil dispersion. For Raman spectrometry, most common solvents are suitable, and ordinary (nonfluorescing) glass specimen cells can be used. The IR region of the electromagnetic spectrum extends from 0.8 to 400  $\mu$ m. From 800 to 2500 nm (0.8 to 2.5  $\mu$ m) is generally considered to be the near-IR (NIR) region; from 2.5 to 25  $\mu$ m (4000 to 400  $\text{cm}^{-1}$ ) is generally considered to be the mid-range (mid-IR) region; and from 25 to 400  $\mu$ m is generally considered to be the far-IR (FIR) region. Unless otherwise specified in the individual monograph, the region from 3800 to 650  $\text{cm}^{-1}$  (2.6 to 15  $\mu$ m) should be used to ascertain compliance with monograph specifications for IR absorption.

Where values for IR line spectra are given in an individual monograph, the letters s, m, and w signify strong, medium, and weak absorption, respectively; sh signifies a shoulder, bd signifies a band, and v means very. The values may vary as much as 0.1  $\mu$ m or 10  $\text{cm}^{-1}$ , depending upon the particular instrument used. Polymorphism gives rise to variations in the IR spectra of many compounds in the solid state. Therefore, when conducting IR absorption tests, if a difference appears in the IR spectra of the analyte and the standard, dissolve equal portions of the test substance and the standard in equal volumes of a suitable solvent, evaporate the solutions to dryness in similar containers under identical conditions, and repeat the test on the residues.

In NIR spectroscopy much of the current interest centers around the ease of analysis. Samples can be analyzed in powder form or by means of reflectance techniques, with little or no preparation. Compliance with in-house specifications can be determined by computerized comparison of spectra with spectra previously obtained from reference materials. Many pharmaceutical materials exhibit low absorptivity in this spectral region, which allows incident near-IR radiation to penetrate samples more deeply than UV, visible, or IR radiation. NIR spectrophotometry may be used to observe matrix modifications and, with proper calibration, may be used in quantitative analysis.

In atomic absorption spectrophotometry, the nature of the solvent and the concentration of solids must be given special consideration. An ideal solvent is one that interferes to a minimal extent in the absorption or emission processes and one that produces neutral atoms in the flame. If there is a significant difference between the surface tension or viscosity of the test solution and standard solution, the solutions are aspirated or atomized at a different rate, causing significant differences in the signals generated. The acid concentration of the solutions also affects the absorption processes. Thus, the solvents used in preparing the test specimen and the standard should be the same or as much alike in these respects as possible, and should yield solutions that are easily aspirated via the specimen tube of the burner-aspirator. Since undissolved solids present in the solutions may give rise to matrix or bulk interferences, the total undissolved solids content in all solutions should be kept below 2% wherever possible.

#### calculations

The application of absorption spectrophotometry in an assay or a test generally requires the use of a Reference Standard. Where such a measurement is specified in an assay, a formula is provided in order to permit calculation of the desired result. A numerical constant is frequently included in the formula. The following derivation is provided to introduce a logical approach to the deduction of the constants appearing in formulas in the assays in many monographs.

The Beer's law relationship is valid for the solutions of both the Reference Standard (S) and the test specimen (U):

$$(1) AS = abCS$$

$$(2) AU = abCU$$

in which AS is the absorbance of the Standard solution of concentration CS; and AU is the absorbance of the test specimen solution of concentration CU. If CS and CU are expressed in the same units and the absorbances of both solutions are measured in matching cells having the same dimensions, the absorptivity, a, and the cell thickness, b, are the same; consequently, the two equations may be combined and rewritten to solve for CU:

$$(3) CU = CS (AU / AS)$$

Quantities of solid test specimens to be taken for analysis are generally specified in mg. Instructions for dilution are given in the assay and, since dilute solutions are used for absorbance measurements, concentrations are usually expressed for convenience in units of  $\mu$ g per mL. Taking a quantity, in mg, of a test specimen of a drug substance or solid dosage form for analysis, it therefore follows that a volume (VU), in L, of solution of concentration CU may be prepared from the amount of test specimen that contains a quantity WU, in mg, of the drug substance [note—CU is numerically the same whether expressed as  $\mu$ g per mL or mg per L], such that:

$$(4) WU = VUCU$$

The form in which the formula appears in the assay in a monograph for a solid article may be derived by substituting CU of equation (3) into equation (4). In summary, the use of equation (4), with due consideration for any unit conversions necessary to achieve equality in equation (5), permits the calculation of the constant factor (VU) occurring in the final formula:

## (5) WU = VUCS (AU / AS)

The same derivation is applicable to formulas that appear in monographs for liquid articles that are assayed by absorption spectrophotometry. For liquid dosage forms, results of calculations are generally expressed in terms of the quantity, in mg, of drug substance in each mL of the article. Thus it is necessary to include in the denominator an additional term, the volume (V), in mL, of the test preparation taken.

Assays in the visible region usually call for comparing concomitantly the absorbance produced by the Assay preparation with that produced by a Standard preparation containing approximately an equal quantity of a USP Reference Standard. In some situations, it is permissible to omit the use of a Reference Standard. This is true where spectrophotometric assays are made with routine frequency, and where a suitable standard curve is available, prepared with the respective USP Reference Standard, and where the substance assayed conforms to Beer's law within the range of about 75% to 125% of the final concentration used in the assay. Under these circumstances, the absorbance found in the assay may be interpolated on the standard curve, and the assay result calculated therefrom.

Such standard curves should be confirmed frequently, and always when a new spectrophotometer or new lots of reagents are put into use.

In spectrophotometric assays that direct the preparation and use of a standard curve, it is permissible and preferable, when the assay is employed infrequently, not to use the standard curve but to make the comparison directly against a quantity of the Reference Standard approximately equal to that taken of the specimen, and similarly treated.

## Fluorescence Spectrophotometry

The measurement of fluorescence is a useful analytical technique. Fluorescence is light emitted from a substance in an excited state that has been reached by the absorption of radiant energy. A substance is said to be fluorescent if it can be made to fluoresce. Many compounds can be assayed by procedures utilizing either their inherent fluorescence or the fluorescence of suitable derivatives.

Test specimens prepared for fluorescence spectrophotometry are usually one-tenth to one-hundredth as concentrated as those used in absorption spectrophotometry, for the following reason. In analytical applications, it is preferable that the fluorescence signal be linearly related to the concentration; but if a test specimen is too concentrated, a significant part of the incoming light is absorbed by the specimen near the cell surface, and the light reaching the center is reduced. That is, the specimen itself acts as an "inner filter." However, fluorescence spectrophotometry is inherently a highly sensitive technique, and concentrations of 10-5 M to 10-7 M frequently are used. It is necessary in any analytical procedure to make a working curve of fluorescence intensity versus concentration in order to establish a linear relationship. All readings should be corrected for a solvent blank.

Fluorescence measurements are sensitive to the presence of dust and other solid particles in the test specimen. Such impurities may reduce the intensity of the exciting beam or give misleading high readings because of multiple reflections in the specimen cell. It is, therefore, wise to eliminate solid particles by centrifugation; filtration also may be used, but some filter papers contain fluorescent impurities.

Temperature regulation is often important in fluorescence spectrophotometry. For some substances, fluorescence efficiency may be reduced by as much as 1% to 2% per degree of temperature rise. In such cases, if maximum precision is desired, temperature-controlled specimen cells are useful. For routine analysis, it may be sufficient to make measurements rapidly enough so that the specimen does not heat up appreciably from exposure to the intense light source. Many fluorescent compounds are light-sensitive. Exposed in a fluorometer, they may be photo-degraded into more or less fluorescent products. Such effects may be detected by observing the detector response in relationship to time, and may be reduced by attenuating the light source with filters or screens.

Change of solvent may markedly affect the intensity and spectral distribution of fluorescence. It is inadvisable, therefore, to alter the solvent specified in established methods without careful preliminary investigation. Many compounds are fluorescent in organic solvents but virtually nonfluorescent in water; thus, a number of solvents should be tried before it is decided whether or not a compound is fluorescent. In many organic solvents, the intensity of fluorescence is increased by elimination of dissolved oxygen, which has a strong quenching effect. Oxygen may be removed by bubbling an inert gas such as nitrogen or helium through the test specimen.

A semiquantitative measure of the strength of fluorescence is given by the ratio of the fluorescence intensity of a test specimen and that of a standard obtained with the same instrumental settings. Frequently, a solution of stated concentration of quinine in 0.1 N sulfuric acid or fluorescein in 0.1 N sodium hydroxide is used as a reference standard.

## Light-Scattering

Turbidity can be measured with a standard photoelectric filter photometer or spectrophotometer, preferably with illumination in the blue portion of the spectrum. Nephelometric measurements require an instrument with a photocell placed so as to receive scattered rather than transmitted light; this geometry applies also to fluorometers, so that, in general, fluorometers can be used as nephelometers, by proper selection of filters. A ratio turbidimeter combines the technology of 90° nephelometry and turbidimetry: it contains photocells that receive and measure scattered light at a 90° angle from the sample as well as receiving and measuring the forward scatter in front of the sample; it also measures light transmitted directly through the sample. Linearity is attained by calculating the ratio of the 90° angle scattered light measurement to the sum of the forward scattered light measurement and the transmitted light measurement. The benefit of using a ratio turbidimetry system is that the measurement of stray light becomes negligible.

In practice, it is advisable to ensure that settling of the particles being measured is negligible. This is usually accomplished by including a protective colloid in the liquid suspending medium. It is important that results be interpreted by comparison of readings with those representing known concentrations of suspended matter, produced under precisely the same conditions.

Turbidimetry or nephelometry may be useful for the measurement of precipitates formed by the interaction of highly dilute solutions of reagents, or other particulate matter, such as suspensions of bacterial cells. In order that consistent results may be achieved, all variables must be carefully controlled. Where such control is possible, extremely dilute suspensions may be measured.

The specimen solute is dissolved in the solvent at several different accurately known concentrations, the choice of concentrations being dependent on the molecular weight of the solute and ranging from 1% for  $M_w = 10,000$  to 0.01% for  $M_w = 1,000,000$ . Each solution must be very carefully cleaned before measurement by repeated filtration through fine filters. A dust particle in the solution vitiates the intensity of the scattered light measured. A criterion for a clear solution is that the dissymmetry, 45°/135° scattered intensity ratio, has attained a minimum.

The turbidity and refractive index of the solutions are measured. From the general 90° light-scattering equation, a plot of  $HC/\bar{M}$  versus C is made and extrapolated to infinite dilution, and the weight-average molecular weight, M, is calculated from the intercept, 1/M.

## Visual Comparison

Where a color or a turbidity comparison is directed, color-comparison tubes that are matched as closely as possible in internal diameter and in all other respects should be used. For color comparison, the tubes should be viewed downward, against a white background, with the aid of a light source directed from beneath the bottoms of the tubes, while for turbidity comparison the tubes should be viewed horizontally, against a dark background, with the aid of a light source directed from the sides of the tubes.

In conducting limit tests that involve a comparison of colors in two like containers (e.g., matched color-comparison tubes), a suitable instrument, rather than the unaided eye, may be used.

## 861 SUTURES—DIAMETER

The gauge for determining the diameter of sutures is of the dead-weight type, mechanical or electrical, and equipped with a direct-reading dial, a digital readout, or a printed readout. Use a gauge graduated to 0.002 mm or smaller. The anvil of the gauge is about 50 mm in diameter, and the presser foot is  $12.70 \pm 0.02$  mm in diameter. The presser foot and moving parts connected therewith are weighted so as to apply a total load of  $210 \pm 3$  g to the specimen. The presser foot and anvil surfaces are plane to within 0.005 mm and parallel to each other to within 0.005 mm. For measuring the diameter of sutures of metric size 0.4 and smaller, remove the additional weight from the presser foot so that the total load on the suture does not exceed 60 g.

**Collagen Absorbable Surgical Suture**— Determine the diameter immediately after removal from the immediate container and without stretching. Lay the strand across the center of the anvil and presser foot, and gently lower the foot until its entire weight rests upon the suture. Measure the diameter of each strand at three points corresponding roughly to one-fourth, one-half, and three-fourths of its length.

**Synthetic Absorbable Surgical Suture**— Proceed as directed for Nonabsorbable Surgical Suture.

**Nonabsorbable Surgical Suture**— Lay the strand across the center of the anvil and presser foot, and gently lower the foot until its entire weight rests upon the suture. Measure nonabsorbable sutures, whether packaged in dry form or in fluid, immediately after removal from the container, without prior drying or conditioning.

Measure the diameter of the suture at three points corresponding roughly to one-fourth, one-half, and three-fourths of its length. In the case of braided suture of sizes larger than 3-0 (metric size 2), make two measurements at each point at right angles to each other, and use the average as the observed diameter at that point.

In measuring multifilament sutures, attach a portion of the designated section of the strand in a fixed clamp in such a way that the strand lies across the center of the anvil. While holding the strand in the same plane as the surface of the anvil, place the strand under tension by suitable means, such as by passing the free end of the strand around a cylinder or a pulley and attaching to the free end a weight of about one-half of the knot-pull limit for the non-sterilized Class I suture of the size concerned, taking care not to permit the strand, if twisted, to untwist. Measure the diameter at the designated points on the strand, and calculate the average diameter likewise as directed.

## 871 SUTURES—NEEDLE ATTACHMENT

Absorbable (collagen) surgical sutures and nonabsorbable surgical sutures with Standard Needle Attachment are such that the needles are firmly attached and are not intended to be separated. Sutures supplied with eyeless needles attached fall into either the category of Standard Needle Attachment or the category of Removable Needle Attachment. Removable Needle Attachment of both absorbable and nonabsorbable surgical sutures is such that the needle may be deliberately separated from the suture by means of a quick tug. Both types

of attachments are tested on equipment as specified under [Tensile Strength](#) (881).

**Procedure**— Clamp each of 5 sutures in the tensiometer so that the needle is in the fixed clamp with all of the swaged portion exposed and in line with the direction of force applied to the suture by the moving clamp. Determine the force required to detach the suture from the needle. In the case of Standard Needle Attachment, the suture may break without needle detachment.

**Standard Needle Attachment**— The requirements are met if neither the average of the 5 values nor any individual value is less than the limit given for the designated size in [Table 1](#).

Table 1. Standard Needle Attachment for Absorbable and Nonabsorbable Sutures

Absorbable Collagen Suture	Nonabsorbable and Synthetic Absorbable Sutures	USP Size	Limits on Needle Attachment			
			Average (in kgf) (Min.)	Individual (in kgf) (Min.)	Average (in N) (Min.)	Individual (in N) (Min.)
0.4	0.1	11-0	0.007	0.005	0.069	0.049
	0.2	10-0	0.014	0.010	0.137	0.098
	0.3	9-0	0.021	0.015	0.206	0.147
	0.4	8-0	0.050	0.025	0.490	0.245
	0.5	7-0	0.080	0.040	0.784	0.392
	0.7	6-0	0.17	0.08	1.67	0.784
	1	5-0	0.23	0.11	2.25	1.08
	1.5	4-0	0.45	0.23	4.41	2.25
	2	3-0	0.68	0.34	6.67	3.33
	3	2-0	1.10	0.45	10.8	4.41
0.5	3.5	0	1.50	0.45	14.7	4.41
	4	3.5	1.80	0.60	17.6	5.88
	5	4	1.80	0.70	17.6	6.86
	6 and larger	5 and larger	2 and larger			

**Removable Needle Attachment**— The requirements are met if the individual values of the 5 sutures are within the limits shown in [Table 2](#). [note—For either type of attachment, if not more than 1 of the individual values falls outside the prescribed limits, repeat the test on an additional 10 sutures: the requirements of the test are met if none of the 10 additional values falls outside the individual limit requirements.]

Table 2. Removable Needle Attachment for Absorbable and Nonabsorbable Sutures

Absorbable Collagen Suture	Nonabsorbable and Synthetic Absorbable Sutures	USP Size	Limits on Needle Attachment			
			Minimum (in kgf)	Maximum (in kgf)	Minimum (in N)	Maximum (in N)
1.5	1	5-0	0.028	1.59	0.274	15.6

2	1.5	4-0	0.028	1.59	0.274	15.6

### 881 TENSILE STRENGTH

Devices for measurement of tensile strength used in the United States may be calibrated in the English units of measure. The following directions are given in metric units with the understanding that the corresponding English equivalents may be used.

#### Surgical Suture

Determine the tensile strength of surgical suture on a motor-driven tensile strength testing machine having suitable clamps for holding the specimen firmly and using either the principle of constant rate of load on specimen or the principle of constant rate of elongation of specimen, as described below. The apparatus has two clamps for holding the strand. One of these clamps is mobile. The clamps are designed so that the strand being tested can be attached without any possibility of slipping. Gauge length is defined as the interior distance between the two clamps. For gauge lengths of 125 to 200 mm, the mobile clamp is driven at a constant rate of elongation of  $30 \pm 5$  cm per minute. For gauge lengths of less than 125 mm, the rate of elongation per minute is adjusted to equal 2 times the gauge length per minute. For example, a 5-cm gauge length has a rate of elongation of 10 cm per minute.

Determine the tensile strength of the suture, whether packaged in dry form or in fluid, promptly after removal from the container, without prior drying or conditioning. Attach one end of the suture to the clamp at the load end of the machine, pass the other end through the opposite clamp, applying sufficient tension so that the specimen is taut between the clamps, and engage the second clamp. Perform as many breaks as are specified in the individual monograph. If the break occurs at the clamp, discard the reading on the specimen.

Procedure for a machine operating on the principle of constant rate of load on specimen— This description applies to the machine known as the Incline Plane Tester.

The carriage used in any test is of a weight such that when the break occurs, the position of the recording pen on the chart is between 20% and 80% of the capacity that may be recorded on the chart. The friction in the carriage is low enough to permit the recording pen to depart from the zero line of the chart at a point not exceeding 2.5% of the capacity of the chart when no specimen is held in the clamps.

For surgical sutures of intermediate and larger sizes, the clamp for holding the specimen is of the roll type, with a flat gripping surface. The roll has a diameter of 19 mm and the flat gripping surface is not less than 25 mm in length. The length of the specimen, when inserted in the clamps, is at least 127 mm from nip to nip. The speed of inclination of the plane of the tester is such that it reaches its full inclination of  $30^\circ$  from the horizontal in  $20 \pm 1$  seconds from the start of the test.

For surgical sutures of small sizes, the suitable clamp has a flat gripping surface of not less than 13 mm in length. The speed of inclination of the plane is such that it reaches its full inclination of  $30^\circ$  from the horizontal in  $60 \pm 5$  seconds from the start of the test.

Except where straight pull (no knot required) is indicated in the suture monograph, tie the test suture into a surgeon's knot with one turn of suture around flexible rubber tubing of 6.5-mm inside diameter and 1.6-mm wall thickness. The surgeon's knot is a square knot in which the free end is first passed twice, instead of once, through the loop, and pulled taut, then passed once through a second loop, and the ends are drawn taut so that a single throw is superimposed upon a double throw. Start the first knot with the left end over the right end, exerting sufficient tension to tie the knot securely. Where the test specimen includes a knot, place the specimen in the testing device with the knot approximately midway between the clamps. Leave the flexible rubber tubing in place for the duration of the test.

Procedure for a machine operating on the principle of constant rate of elongation of specimen— This description applies to any suitable tensile testing machine that operates on the principle of constant rate of elongation of specimen.

Except where straight pull (no knot required) is indicated in the suture monographs, tie the test suture into a simple knot formed by placing one end of a strand held in the right hand over the other end held in the left hand, passing one end over the strand and through the loop so formed, and pulling the knot tight. The specimen is placed in the testing device with the knot approximately midway between the clamps.

#### Textile Fabrics and Films

Determine the tensile strength of textile fabrics, including adhesive tape, on a constant-speed or pendulum type of testing machine of the following general description.

The clamps for holding the specimen are smooth, flat, parallel jaws that are not less than 25 mm in length in the dimension parallel to the direction of application of the load. When the width of the strip being tested does not exceed 19 mm, the jaws of the clamp should be at least 25 mm wide. If the width of the strip is greater than 19 mm and not greater than 44 mm, the width of the jaws of the clamp should be at least 50 mm. If the width of the specimen is greater than 44 mm, cut a 25-mm strip, and use a clamp with jaws not less than 50 mm wide. Round all edges that might have a cutting action on the specimen to a radius of 0.4 mm. The jaws are 76.2 mm apart at the beginning of the test, and they separate at the rate of  $30.5 \text{ cm} \pm 13 \text{ mm}$  per minute. The machine is of such capacity that when the break occurs, the deviation of the pendulum from the vertical is between  $9^\circ$  and  $45^\circ$ .

### 891 THERMAL ANALYSIS

Precisely determined thermodynamic events, such as a change of state, can indicate the identity and purity of drugs. Compendial standards have long been established for the melting or boiling temperatures of substances. These transitions occur at characteristic temperatures, and the compendial standards therefore contribute to the identification of the substances.

Because impurities affect these changes in predictable ways, the same compendial standards contribute to the control of the purity of the substances.

Thermal analysis in the broadest sense is the measurement of physical-chemical properties of materials as a function of temperature. Instrumental methods have largely supplanted older methods dependent on visual inspection and on measurements under fixed or arbitrary conditions, because they are objective, they provide more information, they afford permanent records, and they are generally more sensitive, more precise, and more accurate. Furthermore, they may provide information on crystal perfection, polymorphism, melting

temperature, sublimation, glass transitions, dehydration, evaporation, pyrolysis, solid-solid interactions, and purity. Such data are useful in the characterization of substances with respect to compatibility, stability, packaging, and quality control. The measurements used most often in thermal analysis, i.e., transition temperature, thermogravimetry, and impurity analysis, are described here.

**Transition Temperature**— As a specimen is heated, its uptake (or evolution) of heat can be measured [differential scanning calorimetry (DSC)] or the resulting difference in temperature from that of an inert reference heated identically [differential thermal analysis (DTA)] can be measured. Either technique provides a record of the temperature at which phase changes, glass transitions, or chemical reactions occur. In the case of melting, both an “onset” and a “peak” temperature can be determined objectively and reproducibly, often to within a few tenths of a degree. While these temperatures are useful for characterizing substances, and the difference between the two temperatures is indicative of purity, the values cannot be correlated with subjective, visual “melting-range” values or with constants such as the triple point of the pure material.

A complete description of the conditions employed should accompany each thermogram, including make and model of instrument; record of last calibration; specimen size and identification (including previous thermal history); container; identity, flow rate, and pressure of gaseous atmosphere; direction and rate of temperature change; and instrument and recorder sensitivity.

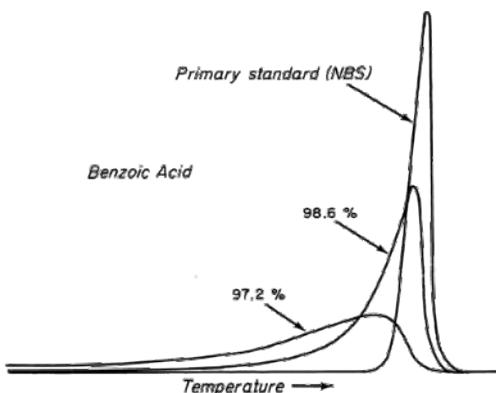

It is appropriate to make a preliminary examination over a wide range of temperature (typically room temperature to decomposition temperature or about 10° to 20° above the melting point) and over a wide range of heating rates (2° to 20° per minute), which may reveal unexpected effects; then a single examination or replicate examinations over a narrow range, bracketing the transition of interest at one or more lower heating rates, can be made. In examining pure crystalline materials, rates as low as 1° per minute may be appropriate, whereas rates of up to 10° per minute are more appropriate for polymeric and other semi-crystalline materials. As the reliability of the measurements varies from one substance to another, statements of the number of significant figures to be used in the reporting of intralaboratory repeatability and of interlaboratory reproducibility cannot be given here, but should be included in the individual monograph.

**Thermogravimetric Analysis**— Thermogravimetric analysis involves the determination of the mass of a specimen as a function of temperature, or time of heating, or both, and when properly applied, provides more useful information than does loss on drying at fixed temperature, often for a fixed time and in what is usually an ill-defined atmosphere. Usually, loss of surface-absorbed solvent can be distinguished from solvent in the crystal lattice and from degradation losses. The measurements can be carried out in atmospheres having controlled humidity and oxygen concentration to reveal interactions with the drug substance, between drug substances, and between active substances and excipients or packaging materials.

While the details depend on the manufacturer, the essential features of the equipment are a recording balance and a programmable heat source. Equipment differs in the ability to handle specimens of various sizes, the means of sensing specimen temperature, and the range of atmosphere control. Calibration is required with all systems, i.e., the mass scale is calibrated by the use of standard weights; calibration of the temperature scale, which is more difficult, involving either variations in positioning of thermocouples and their calibration; or in other systems, calibration involves the use of standard materials because it is assumed that the specimen temperature is the furnace temperature.

Procedural details are specified in order to provide for valid interlaboratory comparison of results. The specimen weight, source, and thermal history are noted. The equipment description covers dimensions and geometry, the materials of the test specimen holder, and the location of the temperature transducer. Alternatively, the make and model number of commercial equipment are specified. In all cases, the calibration record is specified. Data on the temperature environment include the initial and final temperatures and the rate of change or other details if nonlinear. The test atmosphere is critical; the volume, pressure, composition, whether static or dynamic, and if the latter, the flow rate and temperature are specified.

**Eutectic Impurity Analysis**— The basis of any calorimetric purity method is the relationship between the melting and freezing point depression, and the level of impurity. The melting of a compound is characterized by the absorption of latent heat of fusion,  $\Delta H_f$ , at a specific temperature,  $T_0$ . In theory, a melting transition for an absolutely pure crystalline compound should occur within an infinitely narrow range. A broadening of the melting range, due to impurities, provides a sensitive criterion of purity. The effect is apparently visually by examination of thermograms of specimens differing by a few tenths percent in impurity content. A material that is 99% pure is about 20% molten at 3° below the melting point of the pure material (see [accompanying figure](#)).

Superimposed Thermograms Illustrating the Effect of Impurities on DSC Melting Peak Shape

The parameters of melting (melting range,  $\Delta H_f$ , and calculated eutectic purity) are readily obtained from the thermogram of a single melting event using a small test specimen, and the method does not require multiple, precise actual temperature measurements. Thermogram units are directly convertible to heat transfer, millicalories per second.

The lowering of the freezing point in dilute solutions by molecules of nearly equal size is expressed by a modified van't Hoff equation:

$$\frac{dT}{dX_2} = \frac{RT^2}{\Delta H_f} \cdot (K - 1) \quad (1)$$

in which  $T$  = absolute temperature in degrees Kelvin (°K),  $X_2$  = mole fraction of minor component (solute; impurity),  $\Delta H_f$  = molar heat of fusion of the major component,  $R$  = gas constant, and  $K$  = distribution ratio of solute between the solid and liquid phases.

Assuming that the temperature range is small and that no solid solutions are formed ( $K = 0$ ), integration of the van't Hoff equation yields the following relationship between mole fraction of impurity and the melting-point depression:

$$X_2 = \frac{(T_0 - T_m)\Delta H_f}{RT_0^2} \quad (2)$$

in which  $T_o$  = melting point of the pure compound, in  $^{\circ}\text{K}$ , and  $T_m$  = melting point of the test specimen, in  $^{\circ}\text{K}$ .

With no solid solution formation, the concentration of impurity in the liquid phase at any temperature during the melting is inversely proportional to the fraction melted at that temperature, and the melting-point depression is directly proportional to the mole fraction of impurity. A plot of the observed test specimen temperature,  $T_s$ , versus the reciprocal of the fraction melted,  $1/F$ , at temperature  $T_s$ , should yield a straight line with the slope equal to the melting-point depression ( $T_o - T_m$ ). The theoretical melting point of the pure compound is obtained by extrapolation to  $1/F = 0$ :

$$T_s = T_o - \frac{RT_o^2 X_2 (1/F)}{\Delta H_f} \quad (3)$$

Substituting the experimentally obtained values for  $T_o - T_m$ ,  $\Delta H_f$ , and  $T_o$  in Equation 2 yields the mole fraction of the total eutectic impurity, which, when multiplied by 100, gives the mole percentage of total eutectic impurities.

Deviations from the theoretical linear plot also may be due to solid solution formation ( $K \neq 0$ ), so that care must be taken in interpreting the data.

To observe the linear effect of the impurity concentration on the melting-point depression, the impurity must be soluble in the liquid phase or melt of the compound, but insoluble in the solid phase, i.e., no solid solutions are formed. Some chemical similarities are necessary for solubility in the melt. For example, the presence of ionic compounds in neutral organic compounds and the occurrence of thermal decomposition may not be reflected in purity estimates. The extent of these theoretical limitations has been only partially explored.

Impurities present from the synthetic route often are similar to the end product, hence there usually is no problem of solubility in the melt. Impurities consisting of molecules of the same shape, size, and character as those of the major component can fit into the matrix of the major component without disruption of the lattice, forming solid solutions or inclusions; such impurities are not detectable by DSC. Purity estimates are too high in such cases. This is more common with less-ordered crystals as indicated by low heats of fusion.

Impurity levels calculated from thermograms are reproducible and probably reliable within 0.1% for ideal compounds. Melting-point determinations by scanning calorimetry have a reproducibility with a standard deviation of about  $0.2^{\circ}\text{C}$ . Calibration against standards may allow about  $1^{\circ}\text{C}$  accuracy for the melting point, so that this technique is comparable to other procedures.

Compounds that exist in polymorphic form cannot be used in purity determination unless the compound is completely converted to one form. On the other hand, DSC and DTA are inherently useful for detecting, and therefore monitoring, polymorphism.

**Procedure**— The actual procedure and the calculations to be employed are dependent on the particular instrument used. Consult the manufacturer's literature and/or the thermal analysis literature for the most appropriate technique for a given instrument. In any event, it is imperative to keep in mind the limitations of solid solution formation, insolubility in the melt, polymorphism, and decomposition during the analysis.

#### 905 UNIFORMITY OF DOSAGE UNITS

[note—In this chapter, unit and dosage unit are synonymous.]

To ensure the consistency of dosage units, each unit in a batch should have a drug substance content within a narrow range around the label claim. Dosage units are defined as dosage forms containing a single dose or a part of a dose of drug substance in each unit. The uniformity of dosage units specification is not intended to apply to suspensions, emulsions, or gels in unit-dose containers intended for topical administration.

The term "uniformity of dosage unit" is defined as the degree of uniformity in the amount of the drug substance among dosage units. Therefore, the requirements of this chapter apply to each drug substance being comprised in dosage units containing one or more drug substances, unless otherwise specified in the individual monograph.

The uniformity of dosage units can be demonstrated by either of two methods, Content Uniformity or Weight Variation (see [Table 1](#)). The test for Content Uniformity is based on the assay of the individual content of drug substance(s) in a number of individual dosage units to determine whether the individual content is within the limits set. The Content Uniformity method may be applied in all cases. The test for Content Uniformity is required for those dosage forms described in (C1)–(C6) below:

- (C1) coated tablets, other than film-coated tablets containing 25 mg or more of a drug substance that comprises 25% or more (by weight) of one tablet;
- (C2) transdermal systems;
- (C3) suspensions or emulsions or gels in single-unit containers or in soft capsules that are intended for systemic administration only (not for those drug products that are intended for topical administration);
- (C4) inhalations (other than solutions for inhalation packaged in glass or plastic ampuls and intended for use in nebulizers) packaged in premetered dosage units. For inhalers and premetered dosage units labeled for use with a named inhalation device, also see [Aerosols, Nasal Sprays, Metered-Dose Inhalers, and Dry Powder Inhalers](#) (601);
- (C5) solids (including sterile solids) that are packaged in single-unit containers and that contain active or inactive added substances, except that the test for Weight Variation may be applied in the special cases stated in (W3) below; and
- (C6) suppositories.

The test for Weight Variation is applicable for the following dosage forms:

- (W1) solutions for inhalation that are packaged in glass or plastic ampuls and intended for use in nebulizers, and oral solutions packaged in unit-dose containers and into soft capsules;
- (W2) solids (including sterile solids) that are packaged in single-unit containers and contain no added substances, whether active or inactive;
- (W3) solids (including sterile solids) that are packaged in single-unit containers, with or without added substances, whether active or inactive, that have been prepared from true solutions and freeze-dried in the final containers and are labeled to indicate this method of preparation; and
- (W4) hard capsules, uncoated tablets, or film-coated tablets, containing 25 mg or more of a drug substance comprising 25% or more, by weight, of the dosage unit or, in the case of hard capsules, the capsule contents, except that uniformity of other drug substances present in lesser proportions is demonstrated by meeting Content Uniformity requirements.

The test for Content Uniformity is required for all dosage forms not meeting the above conditions for the Weight Variation test. Where compliance with the Content Uniformity test is required, then, by application of the provision for use of alternative methods provided in the General Notices section of this Pharmacopeia, it is possible for manufacturers to ensure this compliance by application of the Weight Variation test where the concentration relative standard deviation (RSD) of the drug substance in the final dosage units is not more than 2%. This RSD determination may be based on the manufacturer's process validation and product development data. The concentration RSD is the RSD of the concentration per dosage unit (w/w or w/v), where concentration per dosage unit equals the assay result per dosage unit divided by the individual dosage unit weight. See the RSD formula in [Table 2](#).

Where the Weight Variation test is used in this way, the product must, if tested, nevertheless comply with the official compendial test for Content Uniformity.

Table 1. Application of Content Uniformity (CU) and Weight Variation (WV) Tests for Dosage Forms

Dosage Form	Type	Subtype	Dose & Ratio of Drug Substance	
			$\geq 25$ mg & $\geq 25\%$	<25 mg or <25%
Tablets	Uncoated		WV	CU
	Coated	Film	WV	CU
		Others	CU	CU
Capsules	Hard		WV	CU
	Soft	Suspension, emulsion, or gel	CU	CU

Suppositories			CU	CU
Others			CU	CU

## CONTENT UNIFORMITY

Select not fewer than 30 units, and proceed as follows for the dosage form designated. Where the amount of drug substance in a single dosage unit differs from that required in the Assay, adjust the degree of dilution of the solutions and/or the volume of aliquots so that the concentration of the drug substances in the final solution is of the same order as that obtained in the Assay procedure; or, in the case of a titrimetric assay, use a titrant of a different concentration, if necessary, so that an adequate volume of titrant is required (see [Titrimetry](#) (541)); see also Procedures under Tests and Assays in the General Notices and Requirements. If any such modifications are made in the Assay procedure set forth in the individual monograph, make the appropriate corresponding changes in the calculation formula and titration factor.

Where a special Procedure for content uniformity is specified in the test for Uniformity of dosage units in the individual monograph, make any necessary correction of the results obtained as follows.

1. Prepare a composite specimen of a sufficient number of dosage units to provide the amount of specimen called for in the Assay in the individual monograph plus the amount required for the special Procedure for content uniformity in the monograph by finely powdering tablets or mixing the contents of capsules or oral solutions, suspensions, emulsions, gels, or solids in single-unit containers to obtain a homogeneous mixture. If a homogeneous mixture cannot be obtained in this manner, use suitable solvents or other procedures to prepare a solution containing all of the drug substance, and use appropriate aliquot portions of this solution for the specified procedures.
2. Assay separate, accurately measured portions of the composite specimen of capsules or tablets or suspensions or inhalations or solids in single-unit containers, both (a) as directed in the Assay, and (b) using the special Procedure for content uniformity in the monograph.
3. Calculate the weight of drug substance equivalent to 1 average dosage unit, by (a) using the results obtained by the Assay procedure, and by (b) using the results obtained by the special procedure.
4. Calculate the correction factor, F, by the formula:

$$F = W/P$$

in which W is the weight of drug substance equivalent to 1 average dosage unit obtained by the Assay procedure, and P is the weight of drug substance equivalent to 1 average dosage unit obtained by the special procedure. If

$$\frac{100|W - P|}{W}$$

is greater than 10, the use of a correction factor is not valid.

5. The correction factor is to be applied only if F is not less than 1.030 nor greater than 1.100, or not less than 0.900 nor greater than 0.970. If F is between 0.970 and 1.030, no correction is required.
6. If F lies between 1.030 and 1.100, or between 0.900 and 0.970, calculate the weight of drug substance in each dosage unit by multiplying each of the weights found using the special procedure by F.

Uncoated, Coated, or Molded Tablets, Capsules, Oral Solutions in Unit-Dose Containers, Suspensions or Emulsions or Gels in Single-Unit Containers (that are intended for systemic administration only), and Solids (including Sterile Solids) in Single-Unit Containers— Assay 10 units individually as directed in the Assay in the individual monograph, unless otherwise specified in the Procedure for content uniformity in the individual monograph. Calculate the acceptance value as directed below.

For oral solutions in unit-dose containers, and for suspensions, emulsions, or gels in single-unit containers that are intended for systemic administration only, conduct the Assay on the amount of well-mixed material that drains from an individual container in not more than 5 seconds, or for highly viscous products, conduct the Assay on the amount of well-mixed material that is obtained by quantitatively removing the contents from an individual container, and express the results as the delivered dose.

Calculation of Acceptance Value— Calculate the acceptance value by the formula:

$$|M - \bar{X}| + ks$$

in which the terms are as defined in [Table 2](#).

Table 2

Variable	Definition	Conditions	Value
X	Mean of individual contents ( $\chi_1, \chi_2, \dots, \chi_n$ ), expressed as a percentage of the label claim		
$\chi_1, \chi_2, \dots, \chi_n$	Individual contents of the units tested, expressed as a percentage of the label claim		
n	Sample size (number of units in a sample)		
k	Acceptability constant	If $n = 10$ , then $k =$ If $n = 30$ , then $k =$	2.4 2.0
s	Sample standard deviation		$\left[ \frac{\sum_{i=1}^n (\chi_i - \bar{X})^2}{n-1} \right]^{\frac{1}{2}}$
RSD	Relative standard deviation (the sample standard deviation expressed as a percentage of the mean)		$\frac{100s}{\bar{X}}$
M (case 1) to be applied when $T \leq 101.5$	Reference value	If $98.5 \leq X \leq 101.5$ , then	$M = X$ ( $AV = ks$ )
		If $X < 98.5$ , then	$M = 98.5\%$ ( $AV = 98.5 - X + ks$ )
		If $X > 101.5$ , then	$M = 101.5\%$ ( $AV = X - 101.5 + ks$ )
M (case 2) to be applied when $T > 101.5$	Reference value	If $98.5 \leq X \leq T$ , then	$M = X$ ( $AV = ks$ )
		If $X < 98.5$ , then	$M = 98.5\%$ ( $AV = 98.5 - X + ks$ )
		If $X > T$ , then	$M = T\%$ ( $AV = X - T + ks$ )
Acceptance value (AV)			general formula: $ M - \bar{X}  + ks$ (Calculations are specified above for the different cases.)
L1	Maximum allowed acceptance value		$L1 = 15.0$ unless otherwise specified in the individual monograph
L2	Maximum allowed range for deviation of each dosage unit tested from the calculated value of M	On the low side, no dosage unit result can be less than $[1 - (0.01)(L2)]M$ , while on the high side no dosage unit result can be greater than $[1 + (0.01)(L2)]M$ . (This is based on an L2 value of 25.0.)	$L2 = 25.0$ unless otherwise specified in the individual monograph
T	Target content per dosage unit at the time of manufacture, expressed as a percentage of the label claim. For purposes of this Pharmacopeia, unless otherwise specified in the individual monograph, T is the average of the limits specified in the potency definition in the individual monograph.		

Suppositories, Transdermal Systems, and Inhalations Packaged in Premetered Dosage Units— [note—Acceptance value calculations are not required for these dosage forms.] Assay 10 units individually as directed in the Assay in the individual monograph, unless otherwise specified in the Procedure for content uniformity.

## WEIGHT VARIATION

Select not fewer than 30 dosage units, and proceed as follows for the dosage form designated. The result of the Assay, obtained as directed in the individual monograph, is designated as result A, expressed as % of label claim (see Calculation of Acceptance Value). Assume that the concentration (weight of drug substance per weight of dosage unit) is uniform. [note—Specimens other than these test units may be drawn from the same batch for assay determinations.]

Uncoated or Film-Coated Tablets— Accurately weigh 10 tablets individually. Calculate the drug substance content, expressed as % of label claim, of each tablet from the weight of the individual tablet and the result of the Assay. Calculate the acceptance value.

Hard Capsules— Accurately weigh 10 capsules individually, taking care to preserve the identity of each capsule. Remove the contents of each capsule by a suitable means. Accurately weigh the emptied shells individually, and calculate for each capsule the net weight of its contents by subtracting the weight of the shell from the respective gross weight. Calculate the drug substance content, expressed as % of label claim, of each capsule from the net weight of the individual capsule content and the result of the Assay. Calculate the acceptance value.

Soft Capsules— Accurately weigh 10 intact capsules individually to obtain their gross weights, taking care to preserve the identity of each capsule. Then cut open the capsules by means of a suitable clean, dry cutting instrument such as scissors or a sharp open blade, and remove the contents by washing with a suitable solvent. Allow the occluded solvent to evaporate from the shells at room temperature over a period of about 30 minutes, taking precautions to avoid uptake or loss of moisture. Weigh the individual shells, and calculate the net contents. Calculate the drug substance content, expressed as % of label claim, in each capsule from the net weight of product removed from the individual capsules and the result of the Assay. Calculate the acceptance value.

Solids (Including Sterile Solids) in Single-Unit Containers— Proceed as directed for Hard Capsules, treating each unit as described therein. Calculate the acceptance value.

Oral Solutions Packaged in Unit-Dose Containers— Accurately weigh the amount of liquid that drains in not more than 5 seconds from each of 10 individual containers. If necessary, compute the equivalent volume after determining the density. Calculate the drug substance content, expressed as % of label claim, in the liquid drained from each unit from the net weight of the individual container content and the result of the Assay. Calculate the acceptance value.

Calculation of Acceptance Value— Calculate the acceptance value as shown in Content Uniformity, except that the individual contents of the units are replaced with the individual estimated contents defined below.

$\bar{x}_1, \bar{x}_2, \dots, \bar{x}_n$  = individual estimated contents of the units tested, where  $\bar{x}_i = w_i \times A / W$ ,  
 $w_1, w_2, \dots, w_n$  = individual weights of the units tested, for weight variation,  
 $A$  = content of drug substance (% of label claim) determined as described in the Assay, and  
 $W$  = mean of individual weights ( $w_1, w_2, \dots, w_n$ ) of the units used in the Assay.

Solutions for Inhalation Packaged in Glass or Plastic Ampuls and Intended for Use in Nebulizers— [note—Acceptance value calculations are not required for these dosage forms.] Accurately weigh 10 containers individually, taking care to preserve the identity of each container. Remove the contents of each container by a suitable means. Accurately weigh the emptied containers individually, and calculate for each container the net weight of its contents by subtracting the weight of the container from the respective gross weight. From the results of the Assay, obtained as directed in the individual monograph, calculate the drug substance content, expressed as % of label claim, in each of the containers.

## CRITERIA

Apply the following criteria, unless otherwise specified in the individual monograph.

Uncoated, Coated, or Molded Tablets, Capsules, Oral Solutions in Unit-Dose Containers, Suspensions or Emulsions or Gels in Single-Unit Containers (that are intended for systemic administration only), and Solids (including Sterile Solids) in Single-Unit Containers— The requirements for dosage uniformity are met if the acceptance value of the first 10 dosage units is less than or equal to L1%. If the acceptance value is greater than L1%, test the next 20 units, and calculate the acceptance value. The requirements are met if the final acceptance value of the 30 dosage units is less than or equal to L1%, and no individual content of any dosage unit is less than  $[1 - (0.01)(L2)] M$  nor more than  $[1 + (0.01)(L2)] M$  as specified in the Calculation of Acceptance Value under Content Uniformity or under Weight Variation. Unless otherwise specified in the individual monograph, L1 is 15.0 and L2 is 25.0.

## Suppositories—

Limit A (if the average of the limits specified in the potency definition in the individual monograph is 100.0 percent or less)—Unless otherwise specified in the individual monograph, the requirements for dosage uniformity are met if the amount of the drug substance in each of the 10 dosage units as determined from the Content Uniformity method lies within the range of 85.0% to 115.0% of the label claim, and the RSD is less than or equal to 6.0%.

If 1 unit is outside the range of 85.0% to 115.0% of label claim, and no unit is outside the range of 75.0% to 125.0% of label claim, or if the RSD is greater than 6.0%, or if both conditions prevail, test 20 additional units. The requirements are met if not more than 1 unit of the 30 is outside the range of 85.0% to 115.0% of label claim, and no unit is outside the range of 75.0% to 125.0% of label claim and the RSD of the 30 dosage units does not exceed 7.8%.

Limit B (if the average of the limits specified in the potency definition in the individual monograph is greater than 100.0 percent)—

1. If the average value of the dosage units tested is 100.0 percent or less, the requirements are as in Limit A.
2. If the average value of the dosage units tested is greater than or equal to the average of the limits specified in the potency definition in the individual monograph, the requirements are as specified under Limit A, except that the words "label claim" are replaced by the words "label claim multiplied by the average of the limits specified in the potency definition in the monograph divided by 100".
3. If the average value of the dosage units tested is between 100 percent and the average of the limits specified in the potency definition in the individual monograph, the requirements are as specified under Limit A, except that the words "label claim" are replaced by the words "label claim multiplied by the average value of the dosage units tested (expressed as a percent of label claim) divided by 100".

## Transdermal Systems and Inhalations Packaged in Premetered Dosage Units—

Limit A (if the average of the limits specified in the potency definition in the individual monograph is 100.0 percent or less)—Unless otherwise specified in the individual monograph, the requirements for dosage uniformity are met if the amount of the drug substance in not fewer than 9 of the 10 dosage units as determined from the Content Uniformity method (or, in the case of solutions for inhalation packaged in glass or plastic ampuls and intended for use in nebulizers, from either the Content Uniformity or the Weight Variation method) lies within the range of 85.0% to 115.0% of label claim, and no unit is outside the range of 75.0% to 125.0% of label claim, and the RSD of the 10 dosage units is less than or equal to 6.0%.

If 2 or 3 dosage units are outside the range of 85.0% to 115.0% of label claim, but not outside the range of 75.0% to 125.0% of label claim, or if the RSD is greater than 6.0% or if both conditions prevail, test 20 additional units. The requirements are met if not more than 3 units of the 30 are outside the range of 85.0% to 115.0% of label claim and no unit is outside the range of 75.0% to 125.0% of label claim, and the RSD of the 30 dosage units does not exceed 7.8%.

Limit B (if the average of the limits specified in the potency definition in the individual monograph is greater than 100.0 percent)—

1. If the average value of the dosage units tested is 100.0 percent or less, the requirements are as in Limit A.
2. If the average value of the dosage units tested is greater than or equal to the average of the limits specified in the potency definition in the individual monograph, the requirements are as specified under Limit A, except that the words "label claim" are replaced by the words "label claim multiplied by the average of the limits specified in the potency definition in the monograph divided by 100".
3. If the average value of the dosage units tested is between 100 percent and the average of the limits specified in the potency definition in the individual monograph, the requirements are as specified under Limit A, except that the words "label claim" are replaced by the words "label claim multiplied by the average value of the dosage units tested (expressed as a percent of label claim) divided by 100".

## 911 VISCOSITY

Viscosity is a property of liquids that is closely related to the resistance to flow. It is defined in terms of the force required to move one plane surface continuously past another under specified steady-state conditions when the space between is filled by the liquid in question. It is defined as the shear stress divided by the rate of shear strain. The basic unit is the poise; however, viscosities commonly encountered represent fractions of the poise, so that the centipoise (1 poise = 100 centipoises) proves to be the more convenient unit. The specifying of temperature is important because viscosity changes with temperature; in general, viscosity decreases as temperature is raised. While on the absolute scale viscosity is measured in poises or centipoises, for convenience the kinematic scale, in which the units are stokes and centistokes (1 stoke = 100 centistokes) commonly is used. To obtain the kinematic viscosity from the absolute viscosity, the latter is divided by the density of the liquid at the same temperature, i.e., kinematic viscosity = (absolute viscosity)/(density). The sizes of the units are such that viscosities in the ordinary ranges are conveniently expressed in centistokes. The approximate viscosity in centistokes at room temperature of ether is 0.2; of water, 1; of kerosene, 2.5; of mineral oil, 20 to 70; and of honey, 10,000.

Absolute viscosity can be measured directly if accurate dimensions of the measuring instruments are known, but it is more common practice to calibrate the instrument with a liquid of known viscosity and to determine the viscosity of the unknown fluid by comparison with that of the known.

Many substances, such as the gums employed in pharmacy, have variable viscosity, and most of them are less resistant to flow at higher flow rates. In such cases, a given set of conditions is selected for measurement, and the measurement obtained is considered to be an apparent viscosity. Since a change in the conditions of measurement would yield a different value for the apparent viscosity of such substances, the instrument dimensions and conditions for measurement must be closely adhered to by the operator.

**Measurement of Viscosity**— The usual method for measurement of viscosity involves the determination of the time required for a given volume of liquid to flow through a capillary. Many capillary-tube viscosimeters have been devised, but Ostwald and Ubbelohde viscosimeters are among the most frequently used. Several types are described, with directions for their use, by the American Society for Testing and Materials (ASTM, D-445). The viscosity of oils is expressed on arbitrary scales that vary from one country to another, there being several corresponding instruments. The most widely used are the Redwood No. I and No. II, the Engler, the Saybolt Universal, and the Saybolt Furol. Each of these instruments uses arbitrary units that bear the name of the instrument. Standard temperatures are adopted as a matter of convenience with these instruments. For the Saybolt instruments, measurements usually are made at 100°F and 210°F; Redwood instruments may be used at several temperatures up to 250°F; and values obtained on the Engler instrument usually are reported at 20°C and 50°C. A particularly convenient and rapid type of instrument is a rotational viscosimeter, which utilizes a bob or spindle immersed in the test specimen and measures the resistance to movement of the rotating part. Different spindles are available for given viscosity ranges, and several rotational speeds generally are available. Other rotational instruments may have a stationary bob and a rotating cup. The Brookfield, Rotovisco, and Stormer viscosimeters are examples of rotating-bob instruments, and the MacMichael is an example of the rotating-cup instrument. Numerous other rotational instruments of advanced design with special devices for reading or recording, and with wide ranges of rotational speed, have been devised.

Where only a particular type of instrument is suitable, the individual monograph so indicates.

For measurement of viscosity or apparent viscosity, the temperature of the substance being measured must be accurately controlled, since small temperature changes may lead to marked changes in viscosity. For usual pharmaceutical purposes, the temperature should be held to within  $\pm 0.1^\circ$ .

**Procedure for Cellulose Derivatives**— Measurement of the viscosity of solutions of the high-viscosity types of methylcellulose is a special case, since they are too viscous for the commonly available viscosimeters. The Ubbelohde viscosimeter may be adapted (cf. ASTM, D-1347) to the measurement of the ranges of viscosity encountered in methylcellulose solutions.

**Calibration of Capillary-Type Viscosimeters**— Determine the viscosimeter constant,  $k$ , for each viscosimeter by the use of an oil of known viscosity.\*

**Ostwald-Type Viscosimeter**— Fill the tube with the exact amount of oil (adjusted to  $20.0 \pm 0.1^\circ$ ) as specified by the manufacturer. Adjust the meniscus of the column of liquid in the capillary tube to the level of the top graduation line with the aid of either pressure or suction. Open both the filling and capillary tubes in order to permit the liquid to flow into the reservoir against atmospheric pressure. [note—Failure to open either of these tubes will yield false values.] Record the time, in seconds, for liquid to flow from the upper mark to the lower mark in the capillary tube.

**Ubbelohde-Type Viscosimeter**— Place a quantity of the oil (adjusted to  $20.0 \pm 0.1^\circ$ ) in the filling tube, and transfer to the capillary tube by gentle suction, taking care to prevent bubble formation in the liquid by keeping the air vent tube closed. Adjust the meniscus of the column of liquid in the capillary tube to the level of the top graduation line. Open both the vent and capillary tubes in order to permit the liquid to flow into the reservoir against atmospheric pressure. [note—Failure to open the vent tube before releasing the capillary tube will yield false values.] Record the time, in seconds, for the liquid to flow from the upper mark to the lower mark in the capillary tube.

## Calculations—

Calculate the viscosimeter constant,  $k$ , from the equation:

$$k = v / d t$$

in which  $v$  is the known viscosity of the liquid in centipoises,  $d$  is the specific gravity of the liquid tested at  $20^\circ/20^\circ$ , and  $t$  is the time in seconds for the liquid to pass from the upper mark to the lower mark.

If a viscosimeter is repaired, it must be recalibrated, since even minor repairs frequently cause significant changes in the value of its constant,  $k$ .

\* Oils of known viscosities may be obtained from the Cannon Instrument Co., Box 16, State College, PA 16801. For methylcellulose, choose an oil the viscosity of which is as close as possible to that of the type of methylcellulose to be determined.

## 921 WATER DETERMINATION

Many Pharmacopeial articles either are hydrates or contain water in adsorbed form. As a result, the determination of the water content is important in demonstrating compliance with

Pharmacopeial standards. Generally one of the methods given below is called for in the individual monograph, depending upon the nature of the article. In rare cases, a choice is allowed between two methods. When the article contains water of hydration, the Method I (Titrimetric), the Method II (Azeotropic), or the Method III (Gravimetric) is employed, as directed in the individual monograph, and the requirement is given under the heading Water.

The heading Loss on drying (see [Loss on Drying](#) 731) is used in those cases where the loss sustained on heating may be not entirely water.

#### METHOD I (TITRIMETRIC)

Determine the water by Method Ia, unless otherwise specified in the individual monograph.

##### Method Ia (Direct Titration)

**Principle**— The titrimetric determination of water is based upon the quantitative reaction of water with an anhydrous solution of sulfur dioxide and iodine in the presence of a buffer that reacts with hydrogen ions.

In the original titrimetric solution, known as Karl Fischer Reagent, the sulfur dioxide and iodine are dissolved in pyridine and methanol. The test specimen may be titrated with the Reagent directly, or the analysis may be carried out by a residual titration procedure. The stoichiometry of the reaction is not exact, and the reproducibility of a determination depends upon such factors as the relative concentrations of the Reagent ingredients, the nature of the inert solvent used to dissolve the test specimen, and the technique used in the particular determination. Therefore, an empirically standardized technique is used in order to achieve the desired accuracy. Precision in the method is governed largely by the extent to which atmospheric moisture is excluded from the system. The titration of water is usually carried out with the use of anhydrous methanol as the solvent for the test specimen; however, other suitable solvents may be used for special or unusual test specimens.

**Apparatus**— Any apparatus may be used that provides for adequate exclusion of atmospheric moisture and determination of the endpoint. In the case of a colorless solution that is titrated directly, the endpoint may be observed visually as a change in color from canary yellow to amber. The reverse is observed in the case of a test specimen that is titrated residually. More commonly, however, the endpoint is determined electrometrically with an apparatus employing a simple electrical circuit that serves to impress about 200 mV of applied potential between a pair of platinum electrodes immersed in the solution to be titrated. At the endpoint of the titration a slight excess of the reagent increases the flow of current to between 50 and 150 microamperes for 30 seconds to 30 minutes, depending upon the solution being titrated. The time is shortest for substances that dissolve in the reagent. With some automatic titrators, the abrupt change in current or potential at the endpoint serves to close a solenoid-operated valve that controls the buret delivering the titrant. Commercially available apparatus generally comprises a closed system consisting of one or two automatic burets and a tightly covered titration vessel fitted with the necessary electrodes and a magnetic stirrer. The air in the system is kept dry with a suitable desiccant, and the titration vessel may be purged by means of a stream of dry nitrogen or current of dry air.

**Reagent**— Prepare the Karl Fischer Reagent as follows. Add 125 g of iodine to a solution containing 670 mL of methanol and 170 mL of pyridine, and cool. Place 100 mL of pyridine in a 250-mL graduated cylinder, and, keeping the pyridine cold in an ice bath, pass in dry sulfur dioxide until the volume reaches 200 mL. Slowly add this solution, with shaking, to the cooled iodine mixture. Shake to dissolve the iodine, transfer the solution to the apparatus, and allow the solution to stand overnight before standardizing. One mL of this solution when freshly prepared is equivalent to approximately 5 mg of water, but it deteriorates gradually; therefore, standardize it within 1 hour before use, or daily if in continuous use. Protect from light while in use. Store any bulk stock of the reagent in a suitably sealed, glass-stoppered container, fully protected from light, and under refrigeration.

A commercially available, stabilized solution of Karl Fischer type reagent may be used. Commercially available reagents containing solvents or bases other than pyridine or alcohols other than methanol may be used also. These may be single solutions or reagents formed in situ by combining the components of the reagents present in two discrete solutions. The diluted Reagent called for in some monographs should be diluted as directed by the manufacturer. Either methanol or other suitable solvent, such as ethylene glycol monomethyl ether, may be used as the diluent.

**Test Preparation**— Unless otherwise specified in the individual monograph, use an accurately weighed or measured amount of the specimen under test estimated to contain 2 to 250 mg of water. The amount of water depends on the water equivalency factor of the Reagent and on the method of endpoint determination. In most cases, the minimum amount of specimen, in mg, can be estimated using the formula:

$$FCV / KF$$

in which F is the water equivalency factor of the Reagent, in mg per mL; C is the used volume, in percent, of the capacity of the buret; V is the buret volume, in mL; and KF is the limit or reasonable expected water content in the sample, in percent. C is between 30% and 100% for manual titration, and between 10% and 100% for the instrumental method endpoint determination.

Where the specimen under test is an aerosol with propellant, store it in a freezer for not less than 2 hours, open the container, and test 10.0 mL of the well-mixed specimen. In titrating the specimen, determine the endpoint at a temperature of 10° or higher.

Where the specimen under test is capsules, use a portion of the mixed contents of not fewer than 4 capsules.

Where the specimen under test is tablets, use powder from not fewer than 4 tablets ground to a fine powder in an atmosphere of temperature and relative humidity known not to influence the results.

Where the monograph specifies that the specimen under test is hygroscopic, use a dry syringe to inject an appropriate volume of methanol, or other suitable solvent, accurately measured, into a tared container, and shake to dissolve the specimen. Using the same syringe, remove the solution from the container and transfer it to a titration vessel prepared as directed for Procedure. Repeat the procedure with a second portion of methanol, or other suitable solvent, accurately measured, add this washing to the titration vessel, and immediately titrate. Determine the water content, in mg, of a portion of solvent of the same total volume as that used to dissolve the specimen and to wash the container and syringe, as directed for Standardization of Water Solution for Residual Titrations, and subtract this value from the water content, in mg, obtained in the titration of the specimen under test. Dry the container and its closure at 100° for 3 hours, allow to cool in a desiccator, and weigh. Determine the weight of specimen tested from the difference in weight from the initial weight of the container.

**Standardization of the Reagent**— Place enough methanol or other suitable solvent in the titration vessel to cover the electrodes, and add sufficient Reagent to give the characteristic endpoint color, or 100 ± 50 microamperes of direct current at about 200 mV of applied potential.

For determination of trace amounts of water (less than 1%), it is preferable to use Reagent with a water equivalency factor of not more than 2.0. Sodium tartrate may be used as a convenient water reference substance. Quickly add 75 to 125 mg of sodium tartrate ( $C_4H_4Na_2O_6 \cdot 2H_2O$ ), accurately weighed by difference, and titrate to the endpoint. The water equivalence factor F, in mg of water per mL of reagent, is given by the formula:

$$2(18.02/230.08)(W/V)$$

in which 18.02 and 230.08 are the molecular weights of water and sodium tartrate dihydrate, respectively; W is the weight, in mg, of sodium tartrate dihydrate; and V is the volume, in mL, of the Reagent consumed in the second titration.

For the precise determination of significant amounts of water (1% or more), use Purified Water as the reference substance. Quickly add between 25 and 250 mg of water, accurately weighed by difference, from a weighing pipet or from a precalibrated syringe or micropipet, the amount taken being governed by the reagent strength and the buret size, as referred to under [Volumetric Apparatus](#) 31. Titrate to the endpoint. Calculate the water equivalence factor, F, in mg of water per mL of reagent, by the formula:

$$W/V$$

in which W is the weight, in mg, of the water; and V is the volume, in mL, of the reagent required.

**Procedure**— Unless otherwise specified, transfer 35 to 40 mL of methanol or other suitable solvent to the titration vessel, and titrate with the Reagent to the electrometric or visual endpoint to consume any moisture that may be present. (Disregard the volume consumed, since it does not enter into the calculations.) Quickly add the Test Preparation, mix, and again titrate with the Reagent to the electrometric or visual endpoint. Calculate the water content of the specimen, in mg, taken by the formula:

$$SF$$

in which S is the volume, in mL, of the Reagent consumed in the second titration; and F is the water equivalence factor of the Reagent.

#### Method Ib (Residual Titration)

**Principle**— See the information given in the section Principle under Method Ia. In the residual titration, excess Reagent is added to the test specimen, sufficient time is allowed for the reaction to reach completion, and the unconsumed Reagent is titrated with a standard solution of water in a solvent such as methanol. The residual titration procedure is applicable generally and avoids the difficulties that may be encountered in the direct titration of substances from which the bound water is released slowly.

**Apparatus, Reagent, and Test Preparation**— Use Method Ia.

**Standardization of Water Solution for Residual Titration**— Prepare a Water Solution by diluting 2 mL of water with methanol or other suitable solvent to 1000 mL. Standardize this solution by titrating 25.0 mL with the Reagent, previously standardized as directed under Standardization of the Reagent. Calculate the water content, in mg per mL, of the Water Solution taken by the formula:

$$VF/25$$

in which V' is the volume of the Reagent consumed, and F is the water equivalence factor of the Reagent. Determine the water content of the Water Solution weekly, and standardize the Reagent against it periodically as needed.

**Procedure**— Where the individual monograph specifies that the water content is to be determined by Method Ib, transfer 35 to 40 mL of methanol or other suitable solvent to the titration vessel, and titrate with the Reagent to the electrometric or visual endpoint. Quickly add the Test Preparation, mix, and add an accurately measured excess of the Reagent. Allow sufficient time for the reaction to reach completion, and titrate the unconsumed Reagent with standardized Water Solution to the electrometric or visual endpoint. Calculate the water content of the specimen, in mg, taken by the formula:

$$F(X' - XR)$$

in which F is the water equivalence factor of the Reagent; X' is the volume, in mL, of the Reagent added after introduction of the specimen; X is the volume, in mL, of standardized Water Solution required to neutralize the unconsumed Reagent; and R is the ratio, V/25 (mL Reagent/mL Water Solution), determined from the Standardization of Water Solution for Residual Titration.

#### Method Ic (Coulometric Titration)

**Principle**— The Karl Fischer reaction is used in the coulometric determination of water. Iodine, however, is not added in the form of a volumetric solution but is produced in an iodide-containing solution by anodic oxidation. The reaction cell usually consists of a large anode compartment and a small cathode compartment that are separated by a diaphragm. Other suitable types of reaction cells (e.g., without diaphragms) may also be used. Each compartment has a platinum electrode that conducts current through the cell. Iodine, which is produced at the anode electrode, immediately reacts with water present in the compartment. When all the water has been consumed, an excess of iodine occurs, which usually is detected electrometrically, thus indicating the endpoint. Moisture is eliminated from the system by pre-electrolysis. Changing the Karl Fischer solution after each determination is not necessary since individual determinations can be carried out in succession in the same reagent solution. A requirement for this method is that each component of the test specimen is compatible with the other components, and no side reactions take place. Samples are usually transferred into the vessel as solutions by means of injection through a septum. Gases can be introduced into the cell by means of a suitable gas inlet tube. Precision in the method is predominantly governed by the extent to which atmospheric moisture is excluded from the system; thus, the introduction of solids into the cell is not recommended, unless elaborate precautions are taken, such as working in a glove-box in an atmosphere of dry inert gas. Control of the system may be monitored by measuring the amount of baseline drift. This method is particularly suited to chemically inert substances like hydrocarbons, alcohols, and ethers. In comparison with the volumetric Karl Fischer titration, coulometry is a micro-method.

**Apparatus**— Any commercially available apparatus consisting of an absolutely tight system fitted with the necessary electrodes and a magnetic stirrer is appropriate. The instrument's microprocessor controls the analytical procedure and displays the results. Calibration of the instrument is not necessary, as the current consumed can be measured absolutely.

**Reagent**— See Reagent under Method Ia.

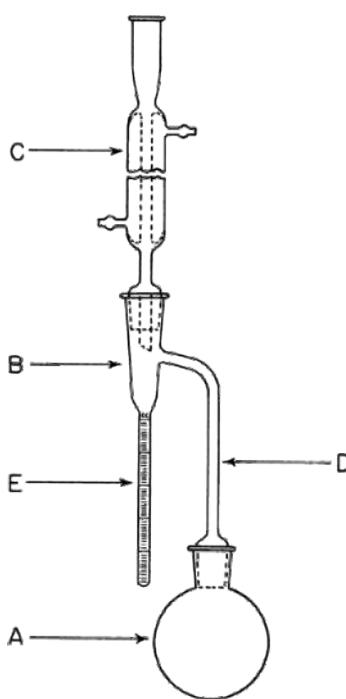

**Test Preparation**— Where the specimen is a soluble solid, dissolve an appropriate quantity, accurately weighed, in anhydrous methanol or other suitable solvents. Liquids may be used as such or as accurately prepared solutions in appropriate anhydrous solvents.

Where the specimen is an insoluble solid, the water may be extracted using a suitable anhydrous solvent from which an appropriate quantity, accurately weighed, may be injected into the anolyte solution. Alternatively an evaporation technique may be used in which water is released and evaporated by heating the specimen in a tube in a stream of dry inert gas, this gas being then passed into the cell.

**Procedure**— Using a dry syringe, quickly inject the Test Preparation, accurately measured and estimated to contain 0.5 to 5 mg of water, or as recommended by the instrument manufacturer into the anolyte, mix, and perform the coulometric titration to the electrometric endpoint. Read the water content of the Test Preparation directly from the instrument's display, and calculate the percentage that is present in the substance. Perform a blank determination, and make any necessary corrections.

#### METHOD II (AZEOTROPIC—TOLUENE DISTILLATION)

**Apparatus**— Use a 500-mL glass flask A connected by means of a trap B to a reflux condenser C by ground glass joints (see [Figure](#)).

Toluene Moisture Apparatus

The critical dimensions of the parts of the apparatus are as follows. The connecting tube D is 9 to 11 mm in internal diameter. The trap is 235 to 240 mm in length. The condenser, if of the straight-tube type, is approximately 400 mm in length and not less than 8 mm in bore diameter. The receiving tube E has a 5-mL capacity, and its cylindrical portion, 146 to 156 mm in length, is graduated in 0.1-mL subdivisions, so that the error of reading is not greater than 0.05 mL for any indicated volume. The source of heat is preferably an electric heater with rheostat control or an oil bath. The upper portion of the flask and the connecting tube may be insulated.

Clean the receiving tube and the condenser with chromic acid cleansing mixture, thoroughly rinse with water, and dry in an oven. Prepare the toluene to be used by first shaking with a small quantity of water, separating the excess water, and distilling the toluene.

Procedure— Place in the dry flask a quantity of the substance, weighed accurately to the nearest centigram, which is expected to yield 2 to 4 mL of water. If the substance is of a pasty character, weigh it in a boat of metal foil of a size that will just pass through the neck of the flask. If the substance is likely to cause bumping, add enough dry, washed sand to cover the bottom of the flask, or a number of capillary melting-point tubes, about 100 mm in length, sealed at the upper end. Place about 200 mL of toluene in the flask, connect the apparatus, and fill the receiving tube E with toluene poured through the top of the condenser. Heat the flask gently for 15 minutes and, when the toluene begins to boil, distill at the rate of about 2 drops per second until most of the water has passed over, then increase the rate of distillation to about 4 drops per second. When the water has apparently all distilled over, rinse the inside of the condenser tube with toluene while brushing down the tube with a tube brush attached to a copper wire and saturated with toluene. Continue the distillation for 5 minutes,

then remove the heat, and allow the receiving tube to cool to room temperature. If any droplets of water adhere to the walls of the receiving tube, scrub them down with a brush consisting of a rubber band wrapped around a copper wire and wetted with toluene. When the water and toluene have separated completely, read the volume of water, and calculate the percentage that was present in the substance.

#### METHOD III (GRAVIMETRIC)

Procedure for Chemicals— Proceed as directed in the individual monograph preparing the chemical as directed under [Loss on Drying \(731\)](#).

Procedure for Biologics— Proceed as directed in the individual monograph.

Procedure for Articles of Botanical Origin— Place about 10 g of the drug, prepared as directed (see Methods of Analysis under [Articles of Botanical Origin \(561\)](#)) and accurately weighed, in a tared evaporating dish. Dry at 105° for 5 hours, and weigh. Continue the drying and weighing at 1-hour intervals until the difference between two successive weighings corresponds to not more than 0.25%.

Auxiliary Information— Please [check for your question in the FAQs](#) before contacting USP.

#### 941 X-RAY DIFFRACTION

Every crystal form of a compound produces its own characteristic X-ray diffraction pattern. These diffraction patterns can be derived either from a single crystal or from a powdered specimen (containing numerous crystals) of the material. The spacings between and the relative intensities of the diffracted maxima can be used for qualitative and quantitative analysis of crystalline materials. Powder diffraction techniques are most commonly employed for routine identification and the determination of relative purity of crystalline materials. Small amounts of impurity, however, are not normally detectable by the X-ray diffraction method, and for quantitative measurements it is necessary to prepare the sample carefully to avoid preferred orientation effects.

The powder methods provide an advantage over other means of analysis in that they are usually nondestructive in nature (specimen preparation is usually limited to grinding to ensure a randomly oriented sample, and deleterious effects of X-rays on solid pharmaceutical compounds are not commonly encountered). The principal use of single-crystal diffraction data is for the determination of molecular weights and analysis of crystal structures at the atomic level. However, diffraction established for a single crystal can be used to support a specific powder pattern as being truly representative of a single phase.

Solids— A solid substance can be classified as being crystalline, noncrystalline, or a mixture of the two forms. In crystalline materials, the molecular or atomic species are ordered in a

...ree-dimensional array, called a lattice, within the solid particles. This ordering of molecular components is lacking in noncrystalline material. Noncrystalline solids sometimes are referred to as glasses or amorphous solids when repetitive order is nonexistent in all three dimensions. It is also possible for order to exist in only one or two dimensions, resulting in mesomorphic phases (liquid crystals). Although crystalline materials are usually considered to have well-defined visible external morphologies (their habits), this is not a necessity for X-ray diffraction analysis.

The relatively random arrangement of molecules in noncrystalline substances makes them poor coherent scatterers of X-rays, resulting in broad, diffuse maxima in diffraction patterns. Their X-ray patterns are quite distinguishable from crystalline specimens, which give sharply defined diffraction patterns.

Many compounds are capable of crystallizing in more than one type of crystal lattice. At any particular temperature and pressure, only one crystalline form (polymorph) is thermodynamically stable. Since the rate of phase transformation of a metastable polymorph to the stable one can be quite slow, it is not uncommon to find several polymorphs of crystalline pharmaceutical compounds existing under normal handling conditions.

In addition to exhibiting polymorphism, many compounds form crystalline solvates in which the solvent molecule is an integral part of the crystal structure. Just as every polymorph has its own characteristic X-ray patterns, so does every solvate. Sometimes the differences in the diffraction patterns of different polymorphs are relatively minor, and must be very carefully evaluated before a definitive conclusion is reached. In some instances, these polymorphs and/or solvates show varying dissolution rates. Therefore, on the time scale of pharmaceutical bioavailability, different total amounts of drug are dissolved, resulting in potential bioinequivalence of the several forms of the drug.

**Fundamental Principles**— A collimated beam of monochromatic X-rays is diffracted in various directions when it impinges upon a rotating crystal or randomly oriented powdered crystal. The crystal acts as a three-dimensional diffraction grating to this radiation. This phenomenon is described by Braggs law, which states that diffraction (constructive interference) can occur only when waves that are scattered from different regions of the crystal, in a specific direction, travel distances differing by integral numbers (n) of the wavelength ( $\lambda$ ). Under such circumstances, the waves are in phase. This condition is described by the Braggs equation:

$$\frac{n\lambda}{2 \sin \theta} = d_{hkl}$$

in which  $d_{hkl}$  denotes the interplanar spacings and  $\theta$  is the angle of diffraction.

A family of planes in space can be indexed by three whole numbers, usually referred to as Miller indices. These indices are the reciprocals, reduced to smallest integers, of the intercepts that a plane makes along the axes corresponding to three nonparallel edges of the unit cell (basic crystallographic unit). The unit cell dimensions are given by the lengths of the spacings along the three axes, a, b, c, and the angles between them,  $\alpha$ ,  $\beta$ , and  $\gamma$ . The interplanar spacing for a specific set of parallel planes  $hkl$  is denoted by  $d_{hkl}$ . Each such family of planes may show higher orders of diffraction where the d values for the related families of planes  $nh$ ,  $nk$ ,  $nl$  are diminished by the factor 1/n (n being an integer: 2, 3, 4, etc.).

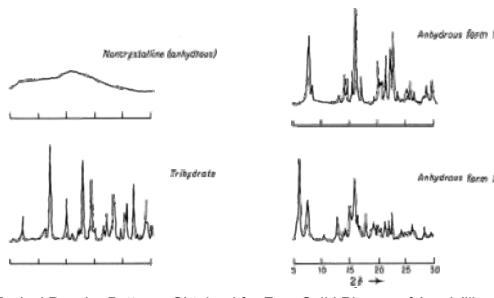

Every set of planes throughout a crystal has a corresponding Braggs diffraction angle associated with it (for a specific  $\lambda$ ).

The amplitude of a diffracted X-ray beam from any set of planes is dependent upon the following atomic properties of the crystal: (1) position of each atom in the unit cell; (2) the respective atomic scattering factors; and (3) the individual thermal motions. Other factors that directly influence the intensities of the diffracted beam are: (1) the intensity and wavelength of the incident radiation; (2) the volume of crystalline specimen; (3) the absorption of the X-radiation by the specimen; and (4) the experimental arrangement utilized to record the intensity data. Thus, the experimental conditions are especially important for measurement of diffraction intensities.

Only a limited number of Braggs planes are in a position to diffract when monochromatized X-rays pass through a single crystal. Techniques of recording the intensities of all of the possible diffracting  $hkl$  planes involve motion of the single crystal and the recording media. Recording of these data is accomplished by photographic techniques (film) or with radiation detectors.

A beam passing through a very large number of small, randomly oriented crystals produces continuous cones of diffracted rays from each set of lattice planes. Each cone corresponds to the diffraction from various planes having a similar interplanar spacing. The intensities of these Braggs reflections are recorded by either film or radiation detectors. The Braggs angle can be measured easily from a film, but the advent of radiation detectors has made possible the construction of diffractometers that read this angle directly. The intensities and d spacings are more conveniently determined with powder diffractometers employing radiation detectors than by film methods. Microphotometers are frequently used for precise intensity measurements of films.

An example of the type of powder patterns obtained for four different solid phases of ampicillin are shown in the accompanying figure.

Typical Powder Patterns Obtained for Four Solid Phases of Ampicillin

These diffraction patterns were derived from a powder diffractometer equipped with a Geiger-Müller detector; nickel-filtered Cu K $\alpha$  radiation was used.

**Radiation**— The principal radiation sources utilized for X-ray diffraction are vacuum tubes utilizing copper, molybdenum, iron, and chromium as anodes; copper X-rays are employed most commonly for organic substances. For each of these radiations there is an element that will filter off the K $\beta$  radiation and permit the K $\alpha$  radiation to pass (nickel is used, in the case of copper radiation). In this manner the radiation is practically monochromatized. The choice of radiation to be used depends upon the absorption characteristics of the material and possible fluorescence by atoms present in the specimen.

**Caution**—Care must be taken in the use of such radiation. Those not familiar with the use of X-ray equipment should seek expert advice. Improper use can result in harmful effects to the operator.

**Test Preparation**— In an attempt to improve randomness in the orientation of crystallites (and, for film techniques, to avoid a grainy pattern), the specimen may be ground in a mortar to a fine powder. Grinding pressure has been known to induce phase transformations; therefore, it is advisable to check the diffraction pattern of the unground sample.

In general, the shapes of many crystalline particles tend to give a specimen that exhibits some degree of preferred orientation in the specimen holder. This is especially evident for needle-like or plate-like crystals where size reduction yields finer needles or platelets. Preferred orientation in the specimen influences the relative intensities of various reflections.

Several specialized handling techniques may be employed to minimize preferred orientation, but further reduction of particle size is often the best approach.

here very accurate measurement of the Braggs angles is necessary, a small amount of an internal standard can be mixed into the specimen. This enables the film or recorder tracing to be calibrated. If comparisons to literature values (including compendial limits) of  $d$  are being made, calibrate the diffractometer. NIST standards are available covering to a  $d$ -value of 0.998 nm. Tetradecanol<sup>1</sup> may be used ( $d$  is 3.963 nm) for larger spacing.

The absorption of the radiation by any specimen is determined by the number and kinds of atoms through which the X-ray beam passes. An organic matrix usually absorbs less of the diffracted radiation than does an inorganic matrix. Therefore, it is important in quantitative studies that standard curves relating amount of material to the intensity of certain  $d$  spacings for that substance be determined in a matrix similar to that in which the substance will be analyzed.

In quantitative analyses of materials, a known amount of standard usually is added to a weighed amount of specimen to be analyzed. This enables the amount of the substance to be determined relative to the amount of standard added. The standard used should have approximately the same density as the specimen and similar absorption characteristics. More important, its diffraction pattern should not overlap to any extent with that of the material to be analyzed. Under these conditions a linear relationship between line intensity and concentration exists. In favorable cases, amounts of crystalline materials as small as 10% may be determined in solid matrices.

Identification of crystalline materials can be accomplished by comparison of X-ray powder diffraction patterns obtained for known<sup>2</sup> materials with those of the unknown. The intensity ratio (ratio of the peak intensity of a particular  $d$  spacing to the intensity of the strongest maxima in the diffraction pattern) and the  $d$  spacing are used in the comparison. If a reference material (e.g., USP Reference Standard) is available, it is preferable to generate a primary reference pattern on the same equipment used for running the unknown sample, and under

the same conditions. For most organic crystals, it is appropriate to record the diffraction pattern to include values for  $2\theta$  that range from as near zero degrees as possible to 40 degrees. Agreement between sample and reference should be within the calibrated precision of the diffractometer for diffraction angle ( $2\theta$ ) values should typically be reproducible to  $\pm 0.10$  degrees), while relative intensities between sample and reference may vary considerably. For other types of samples (e.g., inorganic salts), it may be necessary to extend the  $2\theta$  region scanned to well beyond 40 degrees. It is generally sufficient to scan past the ten strongest reflections identified in the Powder Diffraction File.<sup>2</sup>

General Information

The chapters in this section are information, and aside from excerpts given herein from Federal Acts and regulations that may be applicable, they contain no standards, tests, assays, nor other mandatory specifications, with respect to any Pharmacopeial articles. The excerpts from pertinent Federal Acts and regulations included in this section are placed here inasmuch as they are not of Pharmacopeial authorship. Revisions of the federal requirements that affect these excerpts will be included in USP Supplements as promptly as practical. The official requirements for Pharmacopeial articles are set forth in the General Notices, the individual monographs, and the General Tests and Assays chapters of this Pharmacopeia.

## 1005 ACOUSTIC EMISSION

### INTRODUCTION

Ultrasound techniques can be categorized into two distinct types: acoustic emission (passive mode) and ultrasound spectroscopy (active mode). Both of these techniques have many applications.

The technique of acoustic emission is based on the detection and analysis of sound produced by a process or system. This is essentially equivalent to listening to the process or system, although these sounds are often well above the frequencies that can be detected by the human ear. Generally, frequencies up to about 15 kHz are audible.

In the case of ultrasound spectroscopy, the instrument is designed to generate ultrasound waves across a defined frequency range. These waves travel through the sample and are measured using a receiver. An analogy can be drawn with UV-visible or IR spectroscopy in that the detected ultrasound spectrum reflects changes in velocity or sound attenuation due to the interaction with a sample across a range of frequencies. However, as the scope of this chapter is limited to acoustic emission, ultrasound spectroscopy will not be discussed further.

Acoustic emission is well-known in the study of fracture mechanics and therefore is used extensively by material scientists. It is also widely used as a nondestructive testing technique and is applied routinely for the inspection of aircraft wings, pressure vessels, load-bearing structures, and components. Acoustic emission is also used in the engineering industry for the monitoring of machine tool wear.

In terms of pharmaceutical applications, the dependence of the acoustic emission measurement on physical properties such as particle size, mechanical strength, and cohesivity of solid materials allows the technique to be used for the control and endpoint detection of processes such as high shear granulation, fluid bed drying, milling, and micronization.

### General Principles

Acoustic emissions can propagate by a number of modes. In solids, compressional and shear or transverse modes are important. Compressional modes have the highest velocity and thus reach the acoustic detector (or acoustic emission transducer) first. However, in most process applications of acoustic emission, there are many sources—each producing short bursts of energy—and, consequently, the different modes cannot easily be resolved. The detected signal, for example on the wall of a vessel, is a complex mixture of many overlapping waveforms resulting from many sources and many propagation modes.

At interfaces, depending on the relative acoustic impedance of the two materials, much of the energy is reflected back towards the source. In a fluidized bed, for example, acoustic emissions will only be detected from particles directly impacting the walls of the bed close to the transducer.

A convenient method of studying acoustic emission from processes is to use the “average signal level”. A root mean square-to-direct current (RMS-to-DC) converter may be used to convert the amplitude-modulated (AM) carrier into a more slowly varying DC signal. This is referred to as the average signal level (ASL). The ASL can then be digitally sampled (typically at a sampling frequency of about 50 Hz) and stored electronically for further signal processing.

The simplest way of studying the acoustic data is to examine changes in the ASL. However, other information can be derived from examining the power spectrum of the ASL. The power spectrum is calculated by taking the complex square of the amplitude spectrum and can be obtained by performing a Fast Fourier Transform (FFT) on the digitized raw data record. Power spectra may be averaged to produce a reliable estimate of power spectral density or to give a “fingerprint” of a particular process regime. Interpretation of the power spectrum is complicated by the fact that the acoustic signal originating in the system is distorted by several factors including transmission, reflection, and signal transfer characteristics.

The shape of the power spectrum of the ASL record is a function of the process dynamics. Periodic processes (e.g., mechanical stirring or periodic bubbling of a fluidized bed) show high power at certain discrete frequencies. Random processes show either flicker type properties, where power is inversely proportional to frequency, or white noise type properties in which power is independent of frequency. The amplitude of the power spectrum is also affected by the energy of the acoustic emissions produced by the process. For example, if hard material is being processed, the acoustic emission produced by particle impact will be greater than that produced by soft material.

## INSTRUMENTATION

Generally, piezoelectric sensors are used to detect and quantify the acoustic signals produced by a process. Piezoelectric transducers are constructed from piezoelectric crystalline solids connected to transducer control circuitry by electrical leads. When configured as a detector, an acoustic wave that impinges on the piezoelectric element is transformed into an electrical signal in the transducer control circuitry. When configured as an acoustic generator, an electrical signal applied to the piezoelectric element by the control circuitry creates an acoustic wave that can propagate into the medium to which the transducer is attached. Typically, this means that acoustic emission detectors can also be operated as acoustic wave generators and this feature is used to ensure good sensor performance as described later (see Qualification and Verification of Acoustic Emission Instruments).

In general acoustic emission applications, sensors with different resonance frequencies are often used (e.g., 70 and 190 kHz, although higher frequencies may be more appropriate at smaller scales of operation), incorporating various band-passes. As sound (ultrasound) of the appropriate frequency range reaches these sensors, an electrical signal is generated, the amplitude of which is directly proportional to the energy (amplitude) of the incident sound waves.

These signals are processed through the following:

1. a pre-amplifier (which incorporates signal filtering),
2. an RMS-to-DC converter,
3. a variable gain amplifier, and
4. a PC-based data acquisition board.

The controlling software is also incorporated into the PC.

Acoustic emission equipment generally allows several sensors to be used simultaneously by incorporating multiple electronic channels into a single instrument.

### Signal Processing

The signal from a resonant transducer resembles an AM radio signal. At the resonance frequency of the transducer, the signal consists of a carrier wave that is modulated in amplitude by the process. An RMS-to-DC converter is used to demodulate the signal. The output of this device is the modulation signal or envelope.

The envelope is digitally resampled at a frequency appropriate for the process. For example, 50 Hz is a typical digital sampling rate for a fluid bed drier or high shear granulator.

## FACTORS AFFECTING MEASUREMENT

The following factors can affect the acoustic data obtained and should be considered when installing an acoustic emission system.

1. Failure or Physical Damage—As with any other type of sensor, acoustic emission sensors can fail with time or as a result of physical damage. It is important to check the sensor function as part of routine maintenance of the instrument. If multiple sensors are installed on the same vessel, an active signal can be generated from one sensor and this can be used to check the detection on another sensor. This exercise would ensure that the sensors are detecting the acoustic signals generated by the process. A statistically valid “minimum acceptable acoustic signal” for the sensor(s) should also be determined and monitored at the start, middle, and end of a process to ensure the performance of the sensor(s) during a process run. This may be established from the routine maintenance signal experiments or on the basis of historical data for the sensors.
2. Issues of Sensor Interfacing—Sensors are typically installed on the outer wall of the process vessel. Several types of adhesives (temporary or permanent) can be used to attach the sensor to the vessel wall. Through repeated cleaning and vessel movement, it is possible for the bonding between the sensor and vessel to be compromised. Checking the integrity of the installation should be part of routine maintenance. Similar to item 1 above, an active signal can be used to ensure proper bonding between sensor and vessel and helps to confirm the matching of acoustic impedance.
3. Influence of Mechanical Noise—The use of high frequencies significantly reduces the contribution of mechanical noise to the acoustic signal detected, especially at smaller scales of operation, although it does not eliminate it completely. Testing the effect of various motor settings, for example, can determine if the acoustic signal detected is a function of mechanical noise. If the effect is significant, using higher frequencies may be necessary. Awareness of the contribution of the mechanical noise, no matter how small, is important to consider as the motors age or are replaced.
4. Influence of Vessel Wall Characteristics—Because the sensors are often placed on the outer vessel wall, wall thickness can affect the quality of the signal detected. If the vessel is jacketed, the amplitude of the acoustic signal may be reduced. Adding more sensors on the vessel can improve signal quality. Alternatively, an increase in signal may be obtained by positioning sensor(s) at a location where contact exists between the inner and outer walls, essentially providing a waveguide between the sensor and sound source. Waveguides may also be incorporated into the design of manufacturing equipment to enable utilization of acoustic emission monitoring. Appropriate validation is required to ensure that this does not adversely affect the performance of equipment.
5. Effect of Material Properties—During operation, the acoustic signal collected is a summation of various events occurring within the process. For example, the acoustic signal generated as particles hit the wall in a granulator is a function of the material properties of the granules (i.e., density, size, porosity). Therefore, significant changes to any of these parameters can affect the acoustic signal and the quality of the ensuing prediction.
6. Influence of Process-Related Factors—Similar to item 5 above, the process-related properties (i.e., force of impact, frequency of impact, amount of material) can also affect the acoustic signal and the quality of the ensuing prediction.
7. Impact of Environmental Conditions—Finally, the influence of environmental factors (i.e., temperature, humidity) must also be considered.

The acoustic emission data collected is vessel/equipment specific. It is not advisable to apply a model generated on one piece of equipment to another because the acoustic information can differ as a result of the issues discussed in items 3, 4, and 5 above.

### Qualification and Verification of Acoustic Emission Instruments

A system suitability approach should be taken around instrument performance, establishing optimum measurement configuration, then comparing the instrument performance to the values obtained during routine use to those obtained during installation qualification (IQ).

This approach effectively answers the issues related to sampling because, unlike other on-line analytical systems, the transducers can be optimally positioned and attached to receive the maximum signal without vessel modification.

Sample rates need to comply with the Nyquist sampling theorem, which states that a signal must be sampled at a rate that is twice the highest frequency component in the signal. A low-pass filter should be used to remove the frequency components greater than half the sampling frequency (Nyquist frequency). Failure to comply with this criterion will result in aliasing.

Owing to the nature of the piezoelectric transducers and because resonance frequencies are natural properties of the crystals, it is not necessary to test the variation (reproducibility) or drift in the frequency domain. If other types of transducers are used, this may be necessary. Any gross change in the frequency domain will be recorded as a drop in the power intensity at the resonance frequency, and therefore is covered by the power intensity tests.

The two main areas for instrument performance verification are power intensity and timings. Any change in the signal intensity will affect the raw signal and the ASL and, therefore, will also affect the power spectrum. Changes in power intensity can occur as a result of changes in the process (e.g., variation in hardness or moisture in the particles impacting the vessel wall) or changes in the acoustic conduit from the process to transducer.

Reproducibility of the acoustic conduit should be tested using a second transducer to input a pulse or “ping” at the resonance frequency of the receiving sensor. This reproducibility value represents the noise of the signal and can be used in calculations of limit of detection (LOD) and limit of quantitation (LOQ), where LOD is defined as three times the noise of the signal and LOQ is ten times the noise of the signal. The noise on the background signal level (in acoustic emission this background signal is mainly due to amplifier noise) should be calculated from twenty sequential ASL values acquired at the sampling frequency used for normal operation. This test should be repeated in reverse in order to establish that

statistically similar intensity values can be obtained on both channels.

Short term reproducibility allows the calculation of noise. However, it does not give a measure of integrity of acoustic conduit over time or, more specifically, of changes caused by the process (e.g., variations in adhesive properties with process changes such as heating/cooling). The noise test should be repeated while executing the normal processing parameters (using an empty vessel) and the drift in the ASL should be calculated. Care should be taken to make sure that signal drift (due to normal variation in processing parameters) does not impact chemometric models used for endpoint determination. For trend plots, it should be shown that drift is not statistically significant; otherwise, drift correction will need to be applied. Values for noise, drift, and absolute ASL should be recorded and logged, and the tests re-executed if changes are made to the processing equipment or to the acoustic emission system. If no changes are made, then the tests should be re-executed every month. In this way the quality of the acoustic conduit can be shown to be intact and any changes to the signal intensity isolated and attributed to the process itself.

During routine use, it is recommended that the noise test be executed (as above) before each process run, and that power intensity and noise be calculated. These values should be logged and compared to those generated both during previous use and during installation. Impact of the deviation from previous values will be a function of the prediction model and should be addressed by method validation.

The noise data (from above) can also be used to calculate the time of flight of the pulse. If the pulse activation and signal reception are synchronized, the time taken for the pulse to transmit across the vessel can be measured. This is a good indication of the measurement electronics as well as the overall condition of the acoustic conduit. However, this test should be regarded as a measure of the "system" condition and needs to be executed only if changes have been made to the process equipment or the acoustic emission system, or every 6 months. Correlation of the measured timings with the historical ones should be statistically valid. If not, it is an indicator that the acoustic emission system may need requalification by the instrument manufacturer or supplier, or that there are changes in the acoustic conduit.

All of these tests require the use of an acoustic pulse generated electrically. Failure in any of the above tests could be attributed to the signal generation itself. It is recommended that the electrical pulse generation system be requalified and certified against National Institute of Standards and Technology (NIST) traceable standards every 12 months.

#### DATA ANALYSIS

Acoustic emission from granulators and fluid bed driers is known as continuous acoustic emission. Continuous acoustic emission is aphasic (i.e., there are no starts or stops to the signal). This means that it is unnecessary to use signal processing techniques that preserve phase. Power spectral analysis is a useful technique in processing acoustic emission signals. The information in the power spectra, unlike the raw acoustic emission signals, is coherent in the short term, allowing signal averaging to be performed. This provides a better estimate of power spectral density than that provided by a single power spectrum.

To detect endpoints in batch processes (e.g., granulation or drying endpoint), a qualitative multivariate model is appropriate (e.g., PCA or SIMCA). The following sequence of operations is performed:

1. Training/Calibration—Acoustic emission spectra that are representative of the endpoint condition are obtained.
2. Modeling—A multivariate model describing the distribution of acoustic emission signals at the endpoint condition is created.
3. Prediction—Acoustic emission spectra are compared against the model. The fit to the model (usually expressed in terms of a number of standard deviations) is monitored. As the system approaches the endpoint, the fit improves and completion of the process is established once the model fits predefined criteria. The prediction model is generated from acoustic emission spectra obtained from the process operating under normal conditions. Upsets (e.g., unwanted agglomeration in coaters) are detected by observing statistically valid deviations from the model.

Adaptive modeling has also been proposed for upset detection. This involves generating multivariate models continuously as the acoustic emission signals are acquired. Unusual deviation of the acoustic emission signal indicates the occurrence of a process upset. The advantage of adaptive modeling is that it is not necessary to perform a separate calibration step.

#### GLOSSARY

**Acoustic Emission Transducer**—A solid state device usually incorporating a piezoelectric element to convert the acoustic emission wave to an electrical signal.

**Acoustic Impedance**—Acoustic impedance ( $Z$ ) is defined as  $Z = \rho v$  (where  $\rho$  is density and  $v$  is the sound velocity). It is an important quantity and gives the proportion of sound energy transmitted from one medium to another and the amount of energy reflected at the interface.

**Adaptive Modeling**—A method that predicts the state of a process without the use of a previously generated model (i.e., there is no prior training or calibration step).

**Aliasing**—Spurious low frequency components, appearing in the signal, that are really frequencies above the Nyquist frequency.

**Amplitude**—The magnitude or strength of a varying waveform.

**Average Signal Level (ASL)**—A measure of the average power in an acoustic emission signal.

**Band-Pass**—The range of frequencies within which a component operates.

**Compressional Mode**—A longitudinal mode of acoustic transmission encountered in solids, liquids, and gases.

**Continuous Acoustic Emission**—Acoustic emission signals that cannot be separated in time and are typical of pharmaceutical processes such as granulation and fluid bed drying.

**Flicker Type Properties**—A type of signal associated with many natural processes. The characteristics of flicker noise are that the power of the noise is directly proportional to the signal and has approximately a  $1/f$  ( $f$  = frequency) spectral density distribution.

**Gain**—The amplification factor for a component usually expressed in terms of decibels (dB).

**Gain in dB** =  $20 \log_{10} (\text{Voltageout} / \text{Voltagein})$ .

**Nyquist Frequency**—The Nyquist frequency is defined as half the digital sampling rate and is the highest frequency that can be reproduced faithfully.

**Piezoelectric**—A material which generates an electric field when compressed. Piezoelectric materials are used in the construction of acoustic emission sensors. A common material is PZT (lead zirconium titanate).

**Power Spectrum**—A power spectrum of a signal is a representation of the signal power as a function of frequency. A power spectrum is calculated from the time domain signal by means of the Fast Fourier Transform (FFT) algorithm. It is useful to study acoustic emission signals in the frequency or spectral domain, as the spectrum is often characteristic of the mechanism. Improvements in signal-to-noise ratio can be obtained by averaging a number of power spectra, as they are coherent.

**Power Spectral Density**—The measure of acoustic emission power in each resolution element of the power spectrum.

**Resonance Frequency**—The frequency at which an acoustic emission sensor is most sensitive. Resonant acoustic emission sensors have a clearly defined resonance frequency, but are usually sensitive to other frequencies.

**RMS-to-DC Converter**—An electronic device that converts an alternating signal to a voltage level proportional to the average power in the signal.

**Shear Mode**—A transverse mode of acoustic transmission, encountered only in solids.

**Signal Filtering**—Filtering a signal means attenuating frequencies outside a prescribed range. In acoustic emission work, band-pass filtering is used to improve the signal-to-noise ratio by attenuating noise outside the bandwidth of the sensor. Low-pass filtering is used to remove frequencies higher than the Nyquist frequency in order to prevent aliasing.

**Transverse Mode**—A mode of wave propagation where the displacement of the material is perpendicular to the direction of propagation. These modes are only encountered in solid

materials.

White Noise—The characteristic of white noise is a power spectrum of uniform spectral density and is associated with purely random processes.

## 1010 ANALYTICAL DATA—INTERPRETATION AND TREATMENT

### INTRODUCTION

This chapter provides information regarding acceptable practices for the analysis and consistent interpretation of data obtained from chemical and other analyses. Basic statistical approaches for evaluating data are described, and the treatment of outliers and comparison of analytical methods are discussed in some detail.

NOTE—It should not be inferred that the analysis tools mentioned in this chapter form an exhaustive list. Other, equally valid, statistical methods may be used at the discretion of the manufacturer and other users of this chapter.

Assurance of the quality of pharmaceuticals is accomplished by combining a number of practices, including robust formulation design, validation, testing of starting materials, in-process testing, and final-product testing. Each of these practices is dependent on reliable test methods. In the development process, test procedures are developed and validated to ensure that the manufactured products are thoroughly characterized. Final-product testing provides further assurance that the products are consistently safe, efficacious, and in compliance with their specifications.

Measurements are inherently variable. The variability of biological tests has long been recognized by the USP. For example, the need to consider this variability when analyzing biological test data is addressed under [Design and Analysis of Biological Assays](#) 111. The chemical analysis measurements commonly used to analyze pharmaceuticals are also inherently variable, although less so than those of the biological tests. However, in many instances the acceptance criteria are proportionally tighter, and thus, this smaller allowable variability has to be considered when analyzing data generated using analytical procedures. If the variability of a measurement is not characterized and stated along with the result of the measurement, then the data can only be interpreted in the most limited sense. For example, stating that the difference between the averages from two laboratories when testing a common set of samples is 10% has limited interpretation, in terms of how important such a difference is, without knowledge of the intralaboratory variability.

This chapter provides direction for scientifically acceptable treatment and interpretation of data. Statistical tools that may be helpful in the interpretation of analytical data are described.

Many descriptive statistics, such as the mean and standard deviation, are in common use. Other statistical tools, such as outlier tests, can be performed using several different, scientifically valid approaches, and examples of these tools and their applications are also included. The framework within which the results from a compendial test are interpreted is clearly outlined in Test Results, Statistics, and Standards under General Notices and Requirements. Selected references that might be helpful in obtaining additional information on the statistical tools discussed in this chapter are listed in Appendix F at the end of the chapter. USP does not endorse these citations, and they do not represent an exhaustive list. Further information about many of the methods cited in this chapter may also be found in most statistical textbooks.

### PREREQUISITE LABORATORY PRACTICES AND PRINCIPLES

The sound application of statistical principles to laboratory data requires the assumption that such data have been collected in a traceable (i.e., documented) and unbiased manner. To ensure this, the following practices are beneficial.

#### Sound Record Keeping

Laboratory records are maintained with sufficient detail, so that other equally qualified analysts can reconstruct the experimental conditions and review the results obtained. When collecting data, the data should generally be obtained with more decimal places than the specification requires and rounded only after final calculations are completed as per the General Notices and Requirements.

#### Sampling Considerations

Effective sampling is an important step in the assessment of a quality attribute of a population. The purpose of sampling is to provide representative data (the sample) for estimating the properties of the population. How to attain such a sample depends entirely on the question that is to be answered by the sample data. In general, use of a random process is considered the most appropriate way of selecting a sample. Indeed, a random and independent sample is necessary to ensure that the resulting data produce valid estimates of the properties of the population. Generating a nonrandom or "convenience" sample risks the possibility that the estimates will be biased. The most straightforward type of random sampling is called simple random sampling, a process in which every unit of the population has an equal chance of appearing in the sample. However, sometimes this method of selecting a random sample is not optimal because it cannot guarantee equal representation among factors (i.e., time, location, machine) that may influence the critical properties of the population. For example, if it requires 12 hours to manufacture all of the units in a lot and it is vital that the sample be representative of the entire production process, then taking a simple random sample after the production has been completed may not be appropriate because there can be no guarantee that such a sample will contain a similar number of units made from every time period within the 12-hour process. Instead, it is better to take a systematic random sample whereby a unit is randomly selected from the production process at systematically selected times or locations (e.g., sampling every 30 minutes from the units produced at that time) to ensure that units taken throughout the entire manufacturing process are included in the sample. Another type of random sampling procedure is needed if, for example, a product is filled into vials using four different filling machines. In this case it would be important to capture a random sample of vials from each of the filling machines. A stratified random sample, which randomly samples an equal number of vials from each of the four filling machines, would satisfy this requirement. Regardless of the reason for taking a sample (e.g., batch-release testing), a sampling plan should be established to provide details on how the sample is to be obtained to ensure that the sample is representative of the entirety of the population and that the resulting data have the required sensitivity. The optimal sampling strategy will depend on knowledge of the manufacturing and analytical measurement processes. Once the sampling scheme has been defined, it is likely that the sampling will include some element of random selection. Finally, there must be sufficient sample collected for the original analysis, subsequent verification analyses, and other analyses.

Tests discussed in the remainder of this chapter assume that simple random sampling has been performed.

#### Use of Reference Standards

Where the use of the USP Reference Standard is specified, the USP Reference Standard, or a secondary standard traceable to the USP Reference Standard, is used. Because the assignment of a value to a standard is one of the most important factors that influences the accuracy of an analysis, it is critical that this be done correctly.

#### System Performance Verification

Verifying an acceptable level of performance for an analytical system in routine or continuous use can be a valuable practice. This may be accomplished by analyzing a control sample at appropriate intervals, or using other means, such as, variation among the standards, background signal-to-noise ratios, etc. Attention to the measured parameter, such as charting the results obtained by analysis of a control sample, can signal a change in performance that requires adjustment of the analytical system.

#### Method Validation

All methods are appropriately validated as specified under [Validation of Compendial Procedures](#) 1225. Methods published in the USP-NF have been validated and meet the Current Good Manufacturing Practices regulatory requirement for validation as established in the Code of Federal Regulations. A validated method may be used to test a new

...ulation (such as a new product, dosage form, or process intermediate) only after confirming that the new formulation does not interfere with the accuracy, linearity, or precision of the method. It may not be assumed that a validated method could correctly measure the active ingredient in a formulation that is different from that used in establishing the original validity of the method.

#### MEASUREMENT PRINCIPLES AND VARIATION

All measurements are, at best, estimates of the actual ("true" or "accepted") value for they contain random variability (also referred to as random error) and may also contain systematic variation (bias). Thus, the measured value differs from the actual value because of variability inherent in the measurement. If an array of measurements consists of individual results that are representative of the whole, statistical methods can be used to estimate informative properties of the entirety, and statistical tests are available to investigate whether it is likely that these properties comply with given requirements. The resulting statistical analyses should address the variability associated with the measurement process as well as that of the entity being measured. Statistical measures used to assess the direction and magnitude of these errors include the mean, standard deviation, and expressions derived therefrom, such as the coefficient of variation (CV, also called the relative standard deviation, RSD). The estimated variability can be used to calculate confidence intervals for the mean, or measures of variability, and tolerance intervals capturing a specified proportion of the individual measurements.

The use of statistical measures must be tempered with good judgment, especially with regard to representative sampling. Most of the statistical measures and tests cited in this chapter rely on the assumptions that the distribution of the entire population is represented by a normal distribution and that the analyzed sample is a representative subset of this population. The normal (or Gaussian) distribution is bell-shaped and symmetric about its center and has certain characteristics that are required for these tests to be valid. If the assumption of a normal distribution for the population is not warranted, then normality can often be achieved (at least approximately) through an appropriate transformation of the measurement values. For example, there exist variables that have distributions with longer right tails than left. Such distributions can often be made approximately normal through a log transformation. An alternative approach would be to use "distribution-free" or "nonparametric" statistical procedures that do not require that the shape of the population be that of a normal distribution. When the objective is to construct a confidence interval for the mean or for the difference between two means, for example, then the normality assumption is not as important because of the central limit theorem. However, one must verify normality of data to construct valid confidence intervals for standard deviations and ratios of standard deviations, perform some outlier tests, and construct valid statistical tolerance limits. In the latter case, normality is a critical assumption. Simple graphical methods, such as dot plots, histograms, and normal probability plots, are useful aids for investigating this assumption.

A single analytical measurement may be useful in quality assessment if the sample is from a whole that has been prepared using a well-validated, documented process and if the analytical errors are well known. The obtained analytical result may be qualified by including an estimate of the associated errors. There may be instances when one might consider the use of averaging because the variability associated with an average value is always reduced as compared to the variability in the individual measurements. The choice of whether to use individual measurements or averages will depend upon the use of the measure and its variability. For example, when multiple measurements are obtained on the same sample aliquot, such as from multiple injections of the sample in an HPLC method, it is generally advisable to average the resulting data for the reason discussed above.

Variability is associated with the dispersion of observations around the center of a distribution. The most commonly used statistic to measure the center is the sample mean ( $\bar{x}$ ):

$$\bar{x} = \frac{\sum_{i=1}^n x_i}{n} = \frac{x_1 + x_2 + \dots + x_n}{n}$$

Method variability can be estimated in various ways. The most common and useful assessment of a method's variability is the determination of the standard deviation based on repeated independent<sup>4</sup> measurements of a sample. The sample standard deviation,  $s$ , is calculated by the formula:

$$s = \sqrt{\sum_{i=1}^n (x_i - \bar{x})^2 / (n-1)}$$

in which  $x_i$  is the individual measurement in a set of  $n$  measurements; and  $\bar{x}$  is the mean of all the measurements. The relative standard deviation (RSD) is then calculated as:

$$RSD = \frac{s}{x} \cdot 100\%$$

and expressed as a percentage. If the data requires log transformation to achieve normality (e.g., for biological assays), then alternative methods are available.<sup>2</sup>

A control sample is defined as a homogeneous and stable sample that is tested at specific intervals sufficient to monitor the performance of the method for which it was established. Test data from a control sample can be used to monitor the method variability or be used as part of system suitability requirements.<sup>3</sup> The control sample should be essentially the same as the test sample and should be treated similarly whenever possible. A control chart can be constructed and used to monitor the method performance on a continuing basis as shown under Appendix A.

A precision study should be conducted to provide a better estimate of method variability. The precision study may be designed to determine intermediate precision (which includes the components of both "between run" and "within-run" variability) and repeatability ("within-run" variability). The intermediate precision studies should allow for changes in the experimental conditions that might be expected, such as different analysts, different preparations of reagents, different days, and different instruments. To perform a precision study, the test is repeated several times. Each run must be completely independent of the others to provide accurate estimates of the various components of variability. In addition, within each run, replicates are made in order to estimate repeatability. See an example of a precision study under Appendix B.

A confidence interval for the mean may be considered in the interpretation of data. Such intervals are calculated from several data points using the sample mean ( $\bar{x}$ ) and sample standard deviation ( $s$ ) according to the formula:

$$\left( \bar{x} - t_{\alpha/2, n-1} \frac{s}{\sqrt{n}}, \bar{x} + t_{\alpha/2, n-1} \frac{s}{\sqrt{n}} \right)$$

in which  $t_{\alpha/2, n-1}$  is a statistical number dependent upon the sample size ( $n$ ), the number of degrees of freedom ( $n - 1$ ), and the desired confidence level ( $1 - \alpha$ ). Its values are obtained from published tables of the Student t-distribution. The confidence interval provides an estimate of the range within which the "true" population mean ( $\mu$ ) falls, and it also evaluates the reliability of the sample mean as an estimate of the true mean. If the same experimental set-up were to be replicated over and over and a 95% (for example) confidence

interval for the true mean is calculated each time, then 95% of such intervals would be expected to contain the true mean,  $\mu$ . One cannot say with certainty whether or not the confidence interval derived from a specific set of data actually collected contains  $\mu$ . However, assuming the data represent mutually independent measurements randomly generated from a normally distributed population the procedure used to construct the confidence interval guarantees that 95% of such confidence intervals contain  $\mu$ . Note that it is important to define the population appropriately so that all relevant sources of variation are captured.

## OUTLYING RESULTS

Occasionally, observed analytical results are very different from those expected. Aberrant, anomalous, contaminated, discordant, spurious, suspicious or wild observations; and flyers, rogues, and mavericks are properly called outlying results. Like all laboratory results, these outliers must be documented, interpreted, and managed. Such results may be accurate measurements of the entity being measured, but are very different from what is expected. Alternatively, due to an error in the analytical system, the results may not be typical, even though the entity being measured is typical. When an outlying result is obtained, systematic laboratory and process investigations of the result are conducted to determine if an assignable cause for the result can be established. Factors to be considered when investigating an outlying result include—but are not limited to—human error, instrumentation error, calculation error, and product or component deficiency. If an assignable cause that is not related to a product or component deficiency can be identified, then retesting may be performed on the same sample, if possible, or on a new sample. The precision and accuracy of the method, the Reference Standard, process trends, and the specification limits should all be examined. Data may be invalidated, based on this documented investigation, and eliminated from subsequent calculations.

If no documentable, assignable cause for the outlying laboratory result is found, the result may be tested, as part of the overall investigation, to determine whether it is an outlier. However, careful consideration is warranted when using these tests. Two types of errors may occur with outlier tests: (a) labeling observations as outliers when they really are not; and (b) failing to identify outliers when they truly exist. Any judgment about the acceptability of data in which outliers are observed requires careful interpretation.

"Outlier labeling" is informal recognition of suspicious laboratory values that should be further investigated with more formal methods. The selection of the correct outlier identification technique often depends on the initial recognition of the number and location of the values. Outlier labeling is most often done visually with graphical techniques. "Outlier identification" is the use of statistical significance tests to confirm that the values are inconsistent with the known or assumed statistical model.

When used appropriately, outlier tests are valuable tools for pharmaceutical laboratories. Several tests exist for detecting outliers. Examples illustrating three of these procedures, the Extreme Studentized Deviate (ESD) Test, Dixon's Test, and Hampel's Rule, are presented in [Appendix C](#).

Choosing the appropriate outlier test will depend on the sample size and distributional assumptions. Many of these tests (e.g., the ESD Test) require the assumption that the data generated by the laboratory on the test results can be thought of as a random sample from a population that is normally distributed, possibly after transformation. If a transformation is made to the data, the outlier test is applied to the transformed data. Common transformations include taking the logarithm or square root of the data. Other approaches to handling single and multiple outliers are available and can also be used. These include tests that use robust measures of central tendency and spread, such as the median and median absolute deviation and exploratory data analysis (EDA) methods. "Outlier accommodation" is the use of robust techniques, such as tests based on the order or rank of each data value in the data set instead of the actual data value, to produce results that are not adversely influenced by the presence of outliers. The use of such methods reduces the risks associated with both types of error in the identification of outliers.

"Outlier rejection" is the actual removal of the identified outlier from the data set. However, an outlier test cannot be the sole means for removing an outlying result from the laboratory data. An outlier test may be useful as part of the evaluation of the significance of that result, along with other data. Outlier tests have no applicability in cases where the variability in the product is what is being assessed, such as content uniformity, dissolution, or release-rate determination. In these applications, a value determined to be an outlier may in fact be an accurate result of a nonuniform product. All data, especially outliers, should be kept for future review. Unusual data, when seen in the context of other historical data, are often not unusual after all but reflect the influences of additional sources of variation.

In summary, the rejection or retention of an apparent outlier can be a serious source of bias. The nature of the testing as well as scientific understanding of the manufacturing process and analytical method have to be considered to determine the source of the apparent outlier. An outlier test can never take the place of a thorough laboratory investigation. Rather, it is performed only when the investigation is inconclusive and no deviations in the manufacture or testing of the product were noted. Even if such statistical tests indicate that one or more values are outliers, they should still be retained in the record. Including or excluding outliers in calculations to assess conformance to acceptance criteria should be based on scientific judgment and the internal policies of the manufacturer. It is often useful to perform the calculations with and without the outliers to evaluate their impact.

Outliers that are attributed to measurement process mistakes should be reported (i.e., footnoted), but not included in further statistical calculations. When assessing conformance to a particular acceptance criterion, it is important to define whether the reportable result (the result that is compared to the limits) is an average value, an individual measurement, or something else. If, for example, the acceptance criterion was derived for an average, then it would not be statistically appropriate to require individual measurements to also satisfy the criterion because the variability associated with the average of a series of measurements is smaller than that of any individual measurement.

## COMPARISON OF ANALYTICAL METHODS

It is often necessary to compare two methods to determine if their average results or their variabilities differ by an amount that is deemed important. The goal of a method comparison experiment is to generate adequate data to evaluate the equivalency of the two methods over a range of concentrations. Some of the considerations to be made when performing such comparisons are discussed in this section.

### Precision

Precision is the degree of agreement among individual test results when the analytical method is applied repeatedly to a homogeneous sample. For an alternative method to be considered to have "comparable" precision to that of a current method, its precision (see Analytical Performance Characteristics under [Validation of Compendial Procedures \(1225\)](#)) must not be worse than that of the current method by an amount deemed important. A decrease in precision (or increase in variability) can lead to an increase in the number of results expected to fail required specifications. On the other hand, an alternative method providing improved precision is acceptable.

One way of comparing the precision of two methods is by estimating the variance for each method (the sample variance,  $s^2$ , is the square of the sample standard deviation) and calculating a one-sided upper confidence interval for the ratio of (true) variances, where the ratio is defined as the variance of the alternative method to that of the current method. An example, with this assumption, is outlined under [Appendix D](#). The one-sided upper confidence limit should be compared to an upper limit deemed acceptable, a priori, by the analytical laboratory. If the one-sided upper confidence limit is less than this upper acceptable limit, then the precision of the alternative method is considered acceptable in the sense that the use of the alternative method will not lead to an important loss in precision. Note that if the one-sided upper confidence limit is less than one, then the alternative method has been shown to have improved precision relative to the current method.

The confidence interval method just described is preferred to applying the two-sample F-test to test the statistical significance of the ratio of variances. To perform the two-sample F-test, the calculated ratio of sample variances would be compared to a critical value based on tabulated values of the F distribution for the desired level of confidence and the number of degrees of freedom for each variance. Tables providing F-values are available in most standard statistical textbooks. If the calculated ratio exceeds this critical value, a statistically significant difference in precision is said to exist between the two methods. However, if the calculated ratio is less than the critical value, this does not prove that the methods have the same or equivalent level of precision; but rather that there was not enough evidence to prove that a statistically significant difference did, in fact, exist.

### Accuracy

Comparison of the accuracy (see Analytical Performance Characteristics under [Validation of Compendial Procedures \(1225\)](#)) of methods provides information useful in determining if the new method is equivalent, on the average, to the current method. A simple method for making this comparison is by calculating a confidence interval for the difference in true means, where the difference is estimated by the sample mean of the alternative method minus that of the current method.

The confidence interval should be compared to a lower and upper range deemed acceptable, a priori, by the laboratory. If the confidence interval falls entirely within this acceptable range, then the two methods can be considered equivalent, in the sense that the average difference between them is not of practical concern. The lower and upper limits of the confidence interval only show how large the true difference between the two methods may be, not whether this difference is considered tolerable. Such an assessment can only be

made within the appropriate scientific context.

The confidence interval method just described is preferred to the practice of applying a t-test to test the statistical significance of the difference in averages. One way to perform the t-test is to calculate the confidence interval and to examine whether or not it contains the value zero. The two methods have a statistically significant difference in averages if the confidence interval excludes zero. A statistically significant difference may not be large enough to have practical importance to the laboratory because it may have arisen as a result of highly precise data or a larger sample size. On the other hand, it is possible that no statistically significant difference is found, which happens when the confidence interval includes zero, and yet an important practical difference cannot be ruled out. This might occur, for example, if the data are highly variable or the sample size is too small. Thus, while the outcome of the t-test indicates whether or not a statistically significant difference has been observed, it is not informative with regard to the presence or absence of a difference of practical importance.

#### Determination of Sample Size

Sample size determination is based on the comparison of the accuracy and precision of the two methods<sup>4</sup> and is similar to that for testing hypotheses about average differences in the former case and variance ratios in the latter case, but the meaning of some of the input is different. The first component to be specified is  $\delta$ , the largest acceptable difference between the two methods that, if achieved, still leads to the conclusion of equivalence. That is, if the two methods differ by no more than  $\delta$ , they are considered acceptably similar. The comparison can be two-sided as just expressed, considering a difference of  $\delta$  in either direction, as would be used when comparing means. Alternatively, it can be one-sided as in the case of comparing variances where a decrease in variability is acceptable and equivalency is concluded if the ratio of the variances (new/current, as a proportion) is not more than 1.0 +  $\delta$ . A researcher will need to state  $\delta$  based on knowledge of the current method and/or its use, or it may be calculated. One consideration, when there are specifications to satisfy, is that the new method should not differ by so much from the current method as to risk generating out-of-specification results. One then chooses  $\delta$  to have a low likelihood of this happening by, for example, comparing the distribution of data for the current method to the specification limits. This could be done graphically or by using a tolerance interval, an example of which is given in [Appendix E](#). In general, the choice for  $\delta$  must depend on the scientific requirements of the laboratory.

The next two components relate to the probability of error. The data could lead to a conclusion of similarity when the methods are unacceptably different (as defined by  $\delta$ ). This is called a false positive or Type I error. The error could also be in the other direction; that is, the methods could be similar, but the data do not permit that conclusion. This is a false negative or Type II error. With statistical methods, it is not possible to completely eliminate the possibility of either error. However, by choosing the sample size appropriately, the probability of each of these errors can be made acceptably small. The acceptable maximum probability of a Type I error is commonly denoted as  $\alpha$  and is commonly taken as 5%, but may be chosen differently. The desired maximum probability of a Type II error is commonly denoted by  $\beta$ . Often,  $\beta$  is specified indirectly by choosing a desired level of  $1 - \beta$ , which is called the "power" of the test. In the context of equivalency testing, power is the probability of correctly concluding that two methods are equivalent. Power is commonly taken to be 80% or 90% (corresponding to a  $\beta$  of 20% or 10%), though other values may be chosen. The protocol for the experiment should specify  $\delta$ ,  $\alpha$ , and power. The sample size will depend on all of these components. An example is given in [Appendix E](#). Although [Appendix E](#) determines only a single value, it is often useful to determine a table of sample sizes corresponding to different choices of  $\delta$ ,  $\alpha$ , and power. Such a table often allows for a more informed choice of sample size to better balance the competing priorities of resources and risks (false negative and false positive conclusions).

#### APPENDIX A: CONTROL CHARTS

[Figure 1](#) illustrates a control chart for individual values. There are several different methods for calculating the upper control limit (UCL) and lower control limit (LCL). One method involves the moving range, which is defined as the absolute difference between two consecutive measurements ( $|x_i - x_{i-1}|$ ). These moving ranges are averaged ( MR ) and used in the following formulae:

$$UCL = \bar{x} + 3 \frac{\overline{MR}}{d_2}$$

$$LCL = \bar{x} - 3 \frac{\overline{MR}}{d_2}$$

where  $x$  is the sample mean, and  $d_2$  is a constant commonly used for this type of chart and is based on the number of observations associated with the moving range calculation.

Where  $n = 2$  (two consecutive measurements), as here,  $d_2 = 1.128$ . For the example in [Figure 1](#), the MR was 1.7:

$$UCL = 102.0 + 3 \frac{1.7}{1.128} = 106.5$$

$$LCL = 102.0 - 3 \frac{1.7}{1.128} = 97.5$$

Other methods exist that are better able to detect small shifts in the process mean, such as the cumulative sum (also known as "CUSUM") and exponentially weighted moving average ("EWMA").

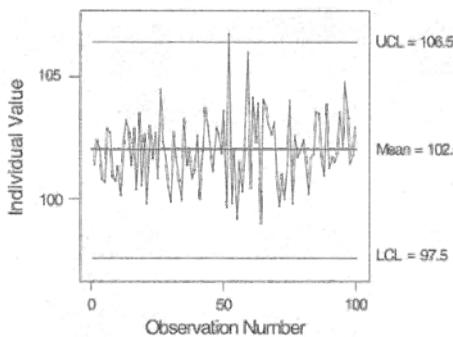

Fig. 1. Individual X or individual measurements control chart for control samples. In this particular example, the mean for all the samples (x) is 102.0, the UCL is 106.5, and the LCL is 97.5.

#### APPENDIX B: PRECISION STUDY

[Table 1](#) displays data collected from a precision study. This study consisted of five independent runs and, within each run, results from three replicates were collected.

Performing an analysis of variance (ANOVA) on the data in [Table 1](#) leads to the ANOVA table ([Table 1A](#)). Because there were an equal number of replicates per run in the precision study, values for VarianceRun and VarianceRep can be derived from the ANOVA table in a straightforward manner. The equations below calculate the variability associated with both the runs and the replicates where the MSwithin represents the “error” or “within-run” mean square, and MSbetween represents the “between-run” mean square.

$$\text{VarianceRep} = \text{MSwithin} = 0.102$$

$$\text{Variance}_{\text{Run}} = \frac{\text{MS}_{\text{between}} - \text{MS}_{\text{within}}}{\# \text{of runs per run}} = \frac{3.550 - 0.102}{3} = 1.149$$

Estimates can still be obtained with unequal replication, but the formulas are more complex. Studying the relative magnitude of the two variance components is important when designing and interpreting a precision study. For example, for these data the between-run component of variability is much larger than the within-run component. This suggests that performing additional runs would be more beneficial to reducing variability than performing more replication per run (see [Table 2](#)).

[Table 2](#) shows the computed variance and RSD of the mean (i.e., of the reportable value) for different combinations of number of runs and number of replicates per run using the following formulas:

*Variance of the mean =*

$$\frac{\text{Variance}_{\text{Run}}}{(\# \text{of runs})} + \frac{\text{Variance}_{\text{Rep}}}{(\# \text{of runs})(\# \text{of reps per run})}$$

*Standard deviation of the mean =  $\sqrt{\text{Variance of the mean}}$*

$$\text{RSD} = \frac{\text{Standard deviation of the mean}}{\text{Average of all results}} \times 100\%$$

For example, the Variance of the mean, Standard deviation of the mean, and RSD of a test involving two runs and three replicates per each run are 0.592, 0.769, and 0.76% respectively, as shown below.

$$\text{Variance of the mean} = \frac{1.149}{2} + \frac{0.102}{(2 \cdot 3)} = 0.592$$

$$\text{Standard deviation of the mean} = \sqrt{0.592} = 0.769$$

$$\text{RSD} = \frac{0.769}{100.96} \times 100\% = 0.76\%$$

Where 100.96 is the mean for all the data points in [Table 1](#). As illustrated in [Table 2](#), increasing the number of runs from one to two provides a more dramatic reduction in the variability of the reportable value than does increasing the number of replicates per run.

No distributional assumptions were made on the data in [Table 1](#) as the purpose of this Appendix is to illustrate the calculations involved in a precision study.

#### APPENDIX C: EXAMPLES OF OUTLIER TESTS FOR ANALYTICAL DATA

Given the following set of 10 measurements: 100.0, 100.1, 100.3, 100.0, 99.7, 99.9, 100.2, 99.5, 100.0, and 95.7 (mean = 99.5, standard deviation = 1.369) are there any outliers?

Generalized Extreme Studentized Deviate (ESD) Test

This is a modified version of the ESD Test that allows for testing up to a previously specified number, r, of outliers from a normally distributed population. Let r equal 2, and n equal 10.

Stage 1 (n = 10)—Normalize each result by subtracting the mean from each value and dividing this difference by the standard deviation (see [Table 3](#)).<sup>5</sup>

Take the absolute value of these results, select the maximum value ( $|R_1| = 2.805$ ), and compare it to a previously specified tabled critical value  $\lambda_1$  (2.290) based on the selected significance level (for example, 5%). The maximum value is larger than the tabled value and is identified as being inconsistent with the remaining data. Sources for  $\lambda$ -values are included in many statistical textbooks. Caution should be exercised when using any statistical table to ensure that the correct notations (i.e., level of acceptable error) are used when extracting table values.

Stage 2 (n = 9)—Remove the observation corresponding to the maximum absolute normalized result from the original data set, so that n is now 9. Again, find the mean and standard

uation ([Table 3](#), right two columns), normalize each value, and take the absolute value of these results. Find the maximum of the absolute values of the 9 normalized results ( $|R_1| = 1.905$ ), and compare it to  $\lambda_2$  (2.215). The maximum value is not larger than the tabled value.

Conclusion— The result from the first stage, 95.7, is declared to be an outlier, but the result from the second stage, 99.5, is not an outlier.

#### Dixon-Type Tests

Similar to the ESD test, the two smallest values will be tested as outliers; again assuming the data come from a single normal population.

Stage 1 ( $n = 10$ )— The results are ordered on the basis of their magnitude (i.e.,  $X_n$  is the largest observation,  $X_{n-1}$  is the second largest, etc., and  $X_1$  is the smallest observation).

Dixon's Test has different ratios based on the sample size (in this example, with  $n = 10$ ), to declare  $X_1$  an outlier, the following ratio,  $r_{11}$ , is calculated by the formula:

$$r_{11} = \frac{X_2 - X_1}{X_{n-1} - X_1}$$

A different ratio would be employed if the largest data point was tested as an outlier. The  $r_{11}$  result is compared to an  $r_{11}, 0.05$  value in a table of critical values. If  $r_{11}$  is greater than  $r_{11}, 0.05$ , then it is declared an outlier. For the above set of data,  $r_{11} = (99.5 - 95.7)/(100.2 - 95.7) = 0.84$ . This ratio is greater than  $r_{11}, 0.05$ , which is 0.534 at the 5% significance level for a two-sided Dixon's Test. Sources for  $r_{11}, 0.05$  values are included in many statistical textbooks.

Stage 2— Remove the smallest observation from the original data set, so that  $n$  is now 9. The same  $r_{11}$  equation is used, but a new critical  $r_{11}, 0.05$  value for  $n = 9$  is needed ( $r_{11}, 0.05 = 0.570$ ). Now  $r_{11} = (99.7 - 99.5)/(100.2 - 99.5) = 0.29$ , which is less than  $r_{11}, 0.05$  and not significant at the 5% level.

Conclusion— Therefore, 95.7 is declared to be an outlier. This stepwise procedure is not an exact procedure for testing for the second outlier as the result of the second test is conditional upon the first. Because the sample size is also reduced in the second stage, the end result is a procedure that usually lacks the sensitivity of the exact procedures that Dixon provides for testing for two outliers simultaneously; however, these procedures are beyond the scope of this Appendix.

#### Hampel's Rule

Step 1— The first step in applying Hampel's Rule is to normalize the data. However, instead of subtracting the mean from each data point and dividing the difference by the standard deviation, the median is subtracted from each data value and the resulting differences are divided by MAD (see below). The calculation of MAD is done in three stages. First, the median is subtracted from each data point. Next, the absolute values of the differences are obtained. These are called the absolute deviations. Finally, the median of the absolute deviations is calculated and multiplied by the constant 1.483 to obtain MAD<sup>6</sup>.

Step 2— The second step is to take the absolute value of the normalized data. Any such result that is greater than 3.5 is declared to be an outlier. [Table 4](#) summarizes the calculations.

The value of 95.7 is again identified as an outlier. This value can then be removed from the data set and Hampel's Rule re-applied to the remaining data. The resulting table is displayed as [Table 5](#). Similar to the previous examples, 99.5 is not considered an outlier.

#### APPENDIX D: COMPARISON OF METHODS—PRECISION

The following example illustrates the calculation of a 90% confidence interval for the ratio of (true) variances for the purpose of comparing the precision of two methods. It is assumed that the underlying distribution of the sample measurements are well-characterized by normal distributions. For this example, assume the laboratory will accept the alternative method if its precision (as measured by the variance) is no more than four-fold greater than that of the current method.

To determine the appropriate sample size for precision, one possible method involves a trial and error approach using the following formula:

$$\text{Power} = \Pr\left[F > \frac{1}{4} F_{\alpha, n-1, n-1}\right]$$

where  $n$  is the smallest sample size required to give the desired power, which is the likelihood of correctly claiming the alternative method has acceptable precision when in fact the two methods have equal precision;  $\alpha$  is the risk of wrongly claiming the alternative method has acceptable precision; and the 4 is the allowed upper limit for an increase in variance.  $F$ -values are found in commonly available tables of critical values of the F-distribution.  $F_{\alpha, n-1, n-1}$  is the upper  $\alpha$  percentile of an F-distribution with  $n - 1$  numerator and  $n - 1$  denominator degrees of freedom; that is, the value exceeded with probability  $\alpha$ . Suppose initially the laboratory guessed a sample size of 11 per method was necessary (10 numerator and denominator degrees of freedom); the power calculation would be as follows:<sup>7</sup>

$$\begin{aligned} \Pr\left[F > \frac{1}{4} F_{\alpha, n-1, n-1}\right] &= \Pr\left[F > \frac{1}{4} F_{.05, 10, 10}\right] = \\ \Pr\left[F > \frac{2.978}{4}\right] &= 0.6311 \end{aligned}$$

In this case the power was only 63%; that is, even if the two methods had exactly equal variances, with only 11 samples per method, there is only a 63% chance that the experiment will lead to data that permit a conclusion of no more than a four-fold increase in variance. Most commonly, sample size is chosen to have at least 80% power, with choices of 90% power or higher also used. To determine the appropriate sample size, various numbers can be tested until a probability is found that exceeds the acceptable limit (e.g., power > 0.90).

For example, the power determination for sample sizes of 12–20 are displayed in [Table 6](#). In this case, the initial guess at a sample size of 11 was not adequate for comparing precision, but 15 samples per method would provide a large enough sample size if 80% power were desired, or 20 per method for 90% power.

Typically the sample size for precision comparisons will be larger than for accuracy comparisons. If the sample size for precision is so large as to be impractical for the laboratory to conduct the study, there are some options. The first is to reconsider the choice of an allowable increase in variance. For larger allowable increases in variance, the required sample size for a fixed power will be smaller. Another alternative is to plan an interim analysis at a smaller sample size, with the possibility of proceeding to a larger sample size if needed. In this case, it is strongly advisable to seek professional help from a statistician.

Now, suppose the laboratory opts for 90% power and obtains the results presented in [Table 7](#) based on the data generated from 20 independent runs per method.

Ratio = Alternative Method Variance/Current Method Variance = 45.0/25.0 = 1.8

Lower Limit of Confidence Interval = Ratio/F.05 = 1.8/2.168 = 0.83

Upper Limit of Confidence Interval = Ratio/F.95 = 1.8/0.461 = 3.90

For this application, a 90% (two-sided) confidence interval is used when a 5% one-sided test is sought. The test is one-sided, because only an increase in standard deviation of the alternative method is of concern. Some care must be exercised in using two-sided intervals in this way, as they must have the property of equal tails—most common intervals have this property. Because the one-side upper confidence limit, 3.90, is less than the allowed limit, 4.0, the study has demonstrated that the alternative method has acceptable precision. If the same results had been obtained from a study with a sample size of 15—as if 80% power had been chosen—the laboratory would not be able to conclude that the alternative method had acceptable precision (upper confidence limit of 4.47).

#### APPENDIX E: COMPARISON OF METHODS—DETERMINING THE LARGEST ACCEPTABLE DIFFERENCE, $\delta$ , BETWEEN TWO METHODS

This Appendix describes one approach to determining the difference,  $\delta$ , between two methods (alternative-current), a difference that, if achieved, still leads to the conclusion of equivalence between the two methods. Without any other prior information to guide the laboratory in the choice of  $\delta$ , it is a reasonable way to proceed. Sample size calculations under various scenarios are discussed in this Appendix.

##### Tolerance Interval Determination

Suppose the process mean and the standard deviation are both unknown, but a sample of size 50 produced a mean and standard deviation of 99.5 and 2.0, respectively. These values were calculated using the last 50 results generated by this specific method for a particular (control) sample. Given this information, the tolerance limits can be calculated by the following formula:

$$x \pm Ks$$

in which  $x$  is the mean;  $s$  is the standard deviation; and  $K$  is based on the level of confidence, the proportion of results to be captured in the interval, and the sample size,  $n$ . Tables providing  $K$  values are available. In this example, the value of  $K$  required to enclose 95% of the population with 95% confidence for 50 samples is 2.382<sup>8</sup>. The tolerance limits are calculated as follows:

$$99.5 \pm 2.382 \times 2.0;$$

hence, the tolerance interval is (94.7, 104.3).

##### Comparison of the Tolerance Limits to the Specification Limits

Assume the specification interval for this method is (90.0, 110.0) and the process mean and standard deviation have not changed since this interval was established. The following quantities can be defined: the lower specification limit (LSL) is 90.0, the upper specification limit (USL) is 110.0, the lower tolerance limit (LTL) is 94.7, and the upper tolerance limit (UTL) is 104.3. Calculate the acceptable difference, ( $\delta$ ), in the following manner:

$$A = LTL - LSL \text{ for } LTL \geq LSL$$

$$(A = 94.7 - 90.0 = 4.7);$$

$$B = USL - UTL \text{ for } USL \geq UTL$$

$$(B = 110.0 - 104.3 = 5.7); \text{ and}$$

$$\delta = \text{minimum } (A, B) = 4.7.$$

Fig. 2. A graph of the quantities calculated above.

With this choice of  $\delta$ , and assuming the two methods have comparable precision, the confidence interval for the difference in means between the two methods (alternative-current) should fall within  $-4.7$  and  $+4.7$  to claim that no important difference exists between the two methods.

Quality control analytical laboratories sometimes deal with 99% tolerance limits, in which cases the interval will widen. Using the previous example, the value of  $K$  required to enclose 99% of the population with 99% confidence for 50 samples is 3.390. The tolerance limits are calculated as follows:

$$99.5 \pm 3.390 \times 2.0;$$

the resultant wider tolerance interval is (92.7, 106.3). Similarly, the new LTL of 92.7 and UTL of 106.3 would produce a smaller  $\delta$ :

$$A = LTL - LSL \text{ for } LTL \geq LSL$$

$$(A = 92.7 - 90.0 = 2.7);$$

$$B = USL - UTL \text{ for } USL \geq UTL$$

$$(B = 110.0 - 106.3 = 3.7); \text{ and}$$

$$\delta = \text{minimum } (A, B) = 2.7.$$

Choosing a larger  $\delta$  leads to a smaller  $n$  but at the cost of increasing the risk of reaching the wrong conclusion.

##### Sample Size

Formulas are available that can be used for a specified  $\delta$ , under the assumption that the population variances are known and equal, to calculate the number of samples required to be tested per method,  $n$ . The level of confidence and power must also be specified. [note—Power refers to the probability of correctly concluding that two identical methods are equivalent.] For example, if  $\delta = 4.7$ , and the two population variances are assumed to equal 4.0, then, for a 5% level test<sup>9</sup> and 80% power (with associated z-values of 1.645 and 1.282, respectively), the sample size is approximated by the following formula:

$$n \geq \frac{2\sigma^2}{\delta^2} (z_{\alpha} + z_{\beta/2})^2$$

$$n \geq \frac{2(4)}{(4.7)^2} (1.645 + 1.282)^2 = 3.10$$

Thus, assuming each method has a population variance,  $\sigma^2$ , of 4.0, the number of samples,  $n$ , required to conclude with 80% probability that the two methods are equivalent (90% confidence interval for the difference in the true means falls between -4.7 and +4.7) when in fact they are identical (the true mean difference is zero) is 4. Because the normal distribution was used in the above formula, 4 is actually a lower bound on the needed sample size. If feasible, one might want to use a larger sample size. Values for  $z$  for common confidence levels are presented in [Table 8](#). The formula above makes three assumptions: 1) the variance used in the sample size calculation is based on a sufficiently large amount of prior data to be treated as known; 2) the prior known variance will be used in the analysis of the new experiment, or the sample size for the new experiment is sufficiently large so that the normal distribution is a good approximation to the t distribution; and 3) the laboratory is confident that there is no actual difference in the means, the most optimistic case. It is not common for all three of these assumptions to hold. The formula above should be treated most often as an initial approximation. Deviations from the three assumptions will lead to a larger required sample size. In general, we recommend seeking assistance from someone familiar with the necessary methods.

When a log transformation is required to achieve normality, the sample size formula needs to be slightly adjusted as shown below. Instead of formulating the problem in terms of the population variance and the largest acceptable difference,  $\delta$ , between the two methods, it now is formulated in terms of the population RSD and the largest acceptable proportional difference between the two methods.

$$n \geq \frac{2\sigma_L^2}{\delta_L^2} \left( z_\alpha + z_{\beta/2} \right)^2$$

where

$$\sigma_L^2 = \log((RSD)^2 + 1)$$

$$\delta_L^2 = (\log(\rho + 1))^2$$

and  $\rho$  represents the largest acceptable proportional difference between the two methods ((alternative-current)/current) and the population RSDs are assumed known and equal.

#### APPENDIX F: ADDITIONAL SOURCES OF INFORMATION

There may be a variety of statistical tests that can be used to evaluate any given set of data. This chapter presents several tests for interpreting and managing analytical data, but many other similar tests could also be employed. The chapter simply illustrates the analysis of data using statistically acceptable methods. As mentioned in the Introduction, specific tests are presented for illustrative purposes, and USP does not endorse any of these tests as the sole approach for handling analytical data. Additional information and alternative tests can be found in the references listed below or in many statistical textbooks.

Alternative	45.0 (6.71)	20	19
Current	25.0 (5.00)	20	19

Table 8. Common Values for a Standard Normal Distribution

	z-values	
Confidence level	One-sided ( $\alpha$ )	Two-sided ( $\alpha/2$ )

99%	2.326	2.576
95%	1.645	1.960
90%	1.282	1.645
80%	0.842	1.282

1 Multiple measurements (or, equivalently, the experimental errors associated with the multiple measurements) are independent from one another when they can be assumed to represent a random sample from the population. In such a sample, the magnitude of one measurement is not influenced by, nor does it influence the magnitude of, any other measurement. Lack of independence implies the measurements are correlated over time or space. Consider the example of a 96-well microtiter plate. Suppose that whenever the unknown causes that produce experimental error lead to a low result (negative error) when a sample is placed in the first column and these same causes would also lead to a low result for a sample placed in the second column, then the two resulting measurements would not be statistically independent. One way to avoid such possibilities would be to randomize the placement of the samples on the plate.

2 When data have been log (base e) transformed to achieve normality, the RSD is:

$$RSD = 100\% \cdot \sqrt{e^{s^2} - 1}$$

This can be reasonably approximated by:

$$RSD = 100\% \cdot (e^s - 1)$$

where  $s$  is the standard deviation of the log (base e) transformed data.

3 See System Suitability under [Chromatography](#) (621).

4 In general, the sample size required to compare the precision of two methods will be greater than that required to compare the accuracy of the methods.

5 The difference between each value and the mean is termed the residual. Other Studentized residual outlier tests exist where the residual, instead of being divided by the standard deviation, can be divided by the standard deviation times the square root of  $n - 1$  divided by  $n$ .

6 Assuming an underlying normal distribution, 1.483 is a constant used so that the resulting MAD is a consistent estimator of the population standard deviation. This means that as the sample size gets larger,  $1.483 \times \text{MAD}$  gets closer to the population standard deviation.

7 This could be calculated using a computer spreadsheet. For example, in Microsoft® Excel the formula would be:  $\text{FDIST}((R/A) * \text{FINV}(\text{alpha}, n - 1, n - 1), n - 1, n - 1)$ , where  $R$  is the ratio of variances at which to determine power (e.g.,  $R = 1$ , which was the value chosen in the power calculations provided in the above table) and  $A$  is the maximum ratio for acceptance (e.g.,  $A = 4$ ).  $\text{alpha}$  is the significance level, typically 0.05.

8 There are existing tables of tolerance factors that give approximate values and thus differ slightly from the values reported here.

9 When testing equivalence, a 5% level test corresponds to a 90% confidence interval.

#### 1015 AUTOMATED RADIOCHEMICAL SYNTHESIS APPARATUS

The preparation and quality control of diagnostic radiopharmaceuticals labeled with the very short-lived positron-emitting nuclides (e.g.,  $^{15}\text{O}$ ,  $^{13}\text{N}$ ,  $^{11}\text{C}$  and  $^{18}\text{F}$  having half-lives of 2, 10, 20, and 110 minutes, respectively), are subject to constraints different from those applicable to therapeutic drugs: (1) Synthesis must be rapid, yet must be arranged to protect the chemist or pharmacist from excessive radiation exposure. (2) Except to a limited extent for  $^{18}\text{F}$ , synthesis must occur at the time of use. (3) With the exception of  $^{18}\text{F}$ , each batch of radiopharmaceutical generally leads to only a single administration.

These factors raise the importance of quality control of the final drug product relative to validation of the synthesis process. Since with few exceptions every dose is individually manufactured, ideally every dose should be subjected to quality control tests for radiochemical purity and other key aspects of quality before administration. Because quality testing of every batch is not possible, batches are selected at regular intervals for examination to establish and completely characterize their radiopharmaceutical purity. This routine and thorough quality testing of selected batches forms the basis of process validation, which is absolutely essential for prospective assessment of batch quality and purity when dealing with such extremely short-lived radiopharmaceuticals. Since radiopharmaceuticals used in positron emission tomography (PET) are administered intravenously or (for radioactive gases) by inhalation, batch-to-batch variability in bioavailability is not an issue. Furthermore, the very small scale of radiopharmaceutical syntheses (almost always less than 1 milligram and often in the microgram range) and the fact that patients generally receive only a single dose of radioactive drug minimize the likelihood of administering harmful amounts of chemical impurities. These statements are not intended to contest the need for quality control in the operation of automated synthesis equipment, but to place the manufacture of positron-emitting radiopharmaceuticals in an appropriate perspective and to reemphasize the overwhelming importance of prospective process validation and finished product quality control.

The routine synthesis of radiopharmaceuticals can result in unnecessarily high radiation doses to personnel. Automated radiochemical synthesis devices have been developed, partly to comply with the concept of reducing personnel radiation exposures to "as low as reasonably achievable" (ALARA). These automated synthesis devices can be more efficient and precise than existing manual methods. Such automated methods are especially useful where a radiochemical synthesis requires repetitive, uniform manipulations on a daily basis.

The products from these automated radiosynthesis devices must meet the same quality assurance criteria as the products obtained by conventional manual syntheses. In the case of positron-emitting radiopharmaceuticals, these criteria will include many of the same determinations used for conventional nuclear medicine radiopharmaceuticals, for example, tests for sterility and bacterial endotoxins. Many of the same limitations apply. Typical analytical procedures such as spectroscopy are not generally applicable because the small amount of product is below the minimum detection level of the method. In all cases, the applicable Pharmacopeial method is the conclusive arbiter (see Procedures under Tests and Assays in the General Notices).

Preparation of Fludeoxyglucose F 18 Injection and other positron-emitting radiopharmaceuticals can be adapted readily to automated synthesis. In general, the equipment required for the manual methods is simpler and less expensive than that used in automated methods but is more labor-intensive. Of special concern are the methods involved in validating the correct performance of an automated apparatus. For a manual procedure, human intervention and correction by inspection can nullify many procedural errors. In an automated system, effective feedback also can begin during the synthesis. For example, radiation detectors can monitor activity at various stages of radiosynthesis. Failure to obtain the appropriate activity could activate an alarm system that would lead to human intervention.

Radiochemicals versus Radiopharmaceuticals— It is appropriate to draw a distinction between a radiochemical and a corresponding radiopharmaceutical. In research PET centers, automated equipment is used to prepare labeled compounds for animal experiments. These radiochemicals are not regarded as radiopharmaceuticals if (1) they are not prepared according to a validated process that provides a high degree of assurance that the preparation meets all established requirements for quality and purity; and (2) have not been certified by qualified personnel (licensed pharmacists and approved physicians) in accordance with published Pharmacopeial methods for individual radiopharmaceuticals.

Automated Equipment— The considerations in this chapter apply to synthesis conducted by general purpose robots and by special purpose apparatus. Both are automated devices used in the synthesis of radiochemicals. The exact method of synthesis device control is variable. Both hard-wired and software-controlled synthesis devices fall under the general designation, and there is a spectrum ranging from traditional manual equipment through semi-automated devices to completely automatic devices.

Common Elements of Automated Synthesis Equipment— To manipulate a chemical apparatus to effect the synthesis of a radiochemical, control of parameters such as time, temperature, pressure, volume, and sequencing are needed. These parameters can be monitored and constrained to fall within certain bounds.

Equipment Quality Assurance— The goal of quality assurance is to help ensure that the subsequent radiopharmaceutical meets Pharmacopeial standards. Although the medical device good manufacturing practice regulations (21 CFR 820) are not applicable, they may be helpful in developing a quality assurance program. As a practical matter this involves documented measurement and control of all relevant physical parameters controlled by the synthesis apparatus.

Routine Quality Control Testing— Routine quality control testing of automated equipment implies periodic testing of all parameters initially certified during the quality assurance qualification. Depending on the criticality and the stability of the parameter setting, testing may be as often as daily. This process performance assessment must be augmented by regular end product testing. For example, variations in the temperature of an oil bath may be acceptable if the radiochemical (end product) can be shown to meet all relevant testing criteria.

Reagent Audit Trail— Materials and reagents used for the synthesis of radiopharmaceuticals should conform to established quality control specifications and tests. Procedures for the testing, storage, and use of these materials should be established. In this context, a reagent is defined as any chemical used in the procedure leading to the final radiochemical product, whereas materials are defined as ancillary supplies (tubing, glassware, vials, etc.). For example, in some processes compressed nitrogen is used to move liquid reagents. In this case, both the nitrogen and the tubing should meet established specifications.

Documentation of Apparatus Parameters— Key synthesis variables should be identified, monitored, and documented. These characteristics include meaningful physical, chemical, electrical, and performance attributes. A method for specifying, testing, and documenting computer software and hardware is especially important for microprocessor- and computer-controlled devices. This program should include periodic generalized testing of the computer hardware. In addition, the software program code should be periodically examined to determine that it has not been modified and that it continues to result in the final product's meeting all specifications. In-process feedback is one means of confirming that the synthesis is under control. Changes to the software code should involve a formal authorization procedure, and changes should be documented.

Each type of radiochemical synthesis device requires a set of specific procedures for testing and monitoring the reliability and reproducibility of the various subsystems that make up the total synthesis system.

It is essential that calibration of each of the components be confirmed according to an established maintenance timetable and that measurements or monitoring be made under actual synthesis conditions.

Delivery times, reagent volumes, temperatures, gas pressures, and rates of flow need to be measured and shown to be stable and reproducible within established limits. Delivery of the reagents and solvents needs to be calibrated periodically. Other components to be routinely calibrated include the radiation detection system and process monitoring sensors and system.

For illustration, elements of system validation of several representative components of an automatic synthetic device are as follows:

Reaction vessels may be cleaned and inspected by an established documented method. The vessels themselves may be numbered and their performance tracked.

Heating and cooling systems (such as oil baths) may be monitored by thermometers or thermocouples. The temperatures may be recorded in a batch sheet, or they may be automatically printed out as part of a computerized log. Maintenance involves periodic calibration.

Gases and gas delivery system performance may be tracked by pressure gauges and flowmeters. Gas purity may be established via supplier certificates of analysis or may be verified by independent testing. Maintenance of gauges and flowmeters involves periodic calibration with standards.

Position-dependent motor performance may be verified by limit switches. Maintenance could involve actual measurement of distance traversed and elapsed time.

Solenoid valves may be checked electrically, by flow and pressure tests.

Heater output is evidenced by proper thermocouple readings. Additional tests could involve resistance measurements.

Reagents may be accepted on the basis of suppliers' certificates of analysis. Alternatively, the chemical could be tested in-house or sent to an independent testing laboratory. Periodic retesting may be necessary depending on stability.

Computer programs may be tested by documenting elapsed time of synthesis, with printouts verifying that all appropriate manipulations occurred, including printing of relevant parameters such as times, temperature, pressures, and activities.

Patterns of activity distribution such as absolute amount of product, percentage yield, and individual impurity activity levels afford the experienced user an opportunity to discern systems failures.

Changes in the Synthesis Method— Some changes in the synthesis apparatus can be considered to be trivial. This category would often include changes not affecting any of the monitored parameters. However, it is important that care be taken to ensure that seemingly innocuous changes do not have an unexpected impact. For example, changes in a comment line of a computer program may result in inadvertently changing or deleting a vital instruction. Any changes in monitored parameters have the potential for changing the process output. If the resultant radiochemical does not meet specifications or if the subsequent radiopharmaceutical does not meet Pharmacopeial criteria, the process change is unacceptable; the fault must be corrected and the process revalidated.

#### 1031 THE BIOCOMPATIBILITY OF MATERIALS USED IN DRUG CONTAINERS, MEDICAL DEVICES, AND IMPLANTS

This chapter provides guidance on the identification and performance of procedures for evaluating the biocompatibility of drug containers, elastomeric closures, medical devices, and implants. Biocompatibility refers to the tendency of these products to remain biologically inert throughout the duration of their contact with the body. The biocompatibility testing procedures referenced in this chapter are designed to detect the nonspecific, biologically reactive, physical or chemical characteristics of medical products or the materials used in their construction. In combination with chemical assays, these biological procedures can be used to detect and identify the inherent or acquired toxicity of medical products prior to or during their manufacturing and processing.

Preclinical testing procedures to evaluate the safety of the elastomers, plastics, or other polymers used in the construction of medical products are referenced or described in the following general chapters: [Injections](#) 1, [Biological Reactivity Tests, In Vitro](#) 87, [Biological Reactivity Tests, In Vivo](#) 88, [Transfusion and Infusion Assemblies and Similar Medical Devices](#) 161, [Elastomeric Closures for Injections](#) 381, and [Containers—Plastics](#) 661. Specific in vitro and in vivo testing procedures to evaluate the biocompatibility

of medical products in patients are described under [Biological Reactivity Tests, In Vitro](#) 87 and under [Biological Reactivity Tests, In Vivo](#) 88.

The procedures used to evaluate the biocompatibility of a medical product or its construction materials have been categorized as a panel of biological effects (toxicity procedures): cytotoxicity, sensitization, irritation or intracutaneous reactivity, acute systemic toxicity, subchronic toxicity (subacute toxicity), genotoxicity, implantation, hemocompatibility, chronic toxicity (extending beyond 10% of the life span of the test animal or beyond 90 days), carcinogenicity, reproductive or developmental toxicity, and biodegradation.<sup>1</sup> The USP general chapters referring to the toxicity procedures for these categories are indicated in [Table 1](#). In addition, pyrogenicity, an area of special toxicity, is evaluated under [Pyrogen Test](#) 151 and under [Bacterial Endotoxins Test](#) 85. There are currently no general chapters that detail sensitization, subchronic toxicity, genotoxicity, chronic toxicity, carcinogenicity, hemotoxicity, reproductive toxicity, or biodegradation testing requirements.

Table 1. Toxicity Procedures in the USP General Chapters

\* Additional general chapters referring to this biological effect include [Transfusion and Infusion Assemblies and Similar Medical Devices](#) 161, [Elastomeric Closures for Injections](#) 381, and [Containers—Plastics](#) 661.

† Additional general chapters referring to this biological effect include [Injections](#) 1, [Transfusion and Infusion Assemblies and Similar Medical Devices](#) 161, [Elastomeric Closures for Injections](#) 381, and [Containers—Plastics](#) 661.

## DRUG CONTAINERS

### Biocompatibility of Plastic and Other Polymeric Drug Containers

Pharmaceutical containers consist of a container and a closure. Plastic containers may consist of polymers that upon extraction do not alter the stability of the contained product or do not exhibit toxicity. The biocompatibility testing requirements for drug containers are stated under [Injections](#) 1 and [Containers—Plastics](#) 661. As directed in these chapters, the plastic or other polymeric portions of these products are tested according to the procedures set forth under [Biological Reactivity Tests, In Vitro](#) 87. A plastic or other polymer that does not meet the requirements of [Biological Reactivity Tests, In Vitro](#) 87 is not a suitable material for a drug container. Materials that meet the in vitro requirements qualify as biocompatible materials without the need for further testing and may be used in the construction of a drug container. If a class designation (classes I–VI) for plastics or other polymers is desired, the appropriate testing procedures are performed as discussed in the section In Vivo Testing and Class Designation.

### Elastomeric Closures

Elastomeric closures are closures that can be pierced by a syringe and maintain their integrity because of their elastic properties. Elastomeric materials may be composed of several chemical entities including fillers, pigments, plasticizers, stabilizers, accelerators, vulcanizing agents, and a natural or a synthetic polymer. These materials are used for manufacturing a product with the desired elastomeric physical properties, and they frequently demonstrate biological reactivity—cellular degeneration and malformation—when tested with in vitro cell cultures.

The biocompatibility of an elastomeric material is evaluated according to the two-stage testing protocol specified in the Biological Test Procedures under [Elastomeric Closures for Injections](#) 381. Unlike plastics or other polymers, an elastomeric material that does not meet the requirements of the first-stage (in vitro) testing may qualify as a biocompatible material by passing the second-stage (in vivo) testing, which consists of the Systemic Injection Test and the Intracutaneous Test described under [Biological Reactivity Tests, In Vivo](#) 88. No class or type distinction is made between elastomeric materials that meet the requirements of the first stage of testing and those that qualify as biocompatible materials by meeting the second-stage requirements. Elastomeric materials are not assigned class I–VI designation.

## MEDICAL DEVICES AND IMPLANTS

Medical devices and implants, labeled nonpyrogenic, in direct or indirect contact with the cardiovascular system or other soft body tissues, meet the requirements described under [Transfusion and Infusion Assemblies and Similar Medical Devices](#) 161. The products listed in this chapter that meet the criteria are solution administration sets, extension sets, transfer sets, blood administration sets, intravenous catheters, dialyzers and dialysis tubing and accessories, transfusion and infusion assemblies, and intramuscular drug delivery catheters. The outlined criteria do not apply to medical products such as orthopedic products, latex gloves, and wound dressings.

The testing requirements described or referenced under [Transfusion and Infusion Assemblies and Similar Medical Devices](#) 161 include Sterility, Bacterial endotoxins, Pyrogen, and Other requirements. A procedure to evaluate the presence of bacterial endotoxins is set forth under [Bacterial Endotoxins Test](#) 85, and the limits are set in [Bacterial Endotoxins](#) under [Transfusion and Infusion Assemblies and Similar Medical Devices](#) 161. For devices that cannot be tested by the [Bacterial Endotoxins Test](#) 85 because of nonremovable inhibition or enhancement, the [Pyrogen Test](#) 151 is applied. The procedures for evaluating medical devices purported to contain sterile pathways are set forth in [Sterile Devices](#) under [Sterility Tests](#) 71. A procedure for evaluating the safety of medical devices is set forth in the Safety Test under [Biological Reactivity Tests, In Vivo](#) 88.

The plastic or other polymer components of medical devices meet the requirements specified for plastics and other polymers under [Containers—Plastics](#) 661; those made of elastomers meet the requirements under [Elastomeric Closures for Injections](#) 381. As directed in these chapters, the biocompatibility of the plastic, other polymeric, and elastomeric portions of these products are tested according to the procedures described under [Biological Reactivity Tests, In Vitro](#) 87. If a class designation for a plastic or other polymer is also required, the appropriate testing procedures described under [Biological Reactivity Tests, In Vivo](#) 88 are performed.

As required for elastomeric closures, elastomeric materials that do not meet the in vitro requirements may qualify as biocompatible materials and may be used in the construction of medical devices if they meet the requirements of the Systemic Injection Test and the Intracutaneous Test under [Biological Reactivity Tests, In Vivo](#) 88. As required for drug containers, plastics and other polymers that do not meet the in vitro testing requirements are not suitable materials for use in medical devices.

## IN VITRO TESTING, IN VIVO TESTING, AND CLASS DESIGNATION FOR PLASTICS AND OTHER POLYMERS

The testing requirements specified under [Biological Reactivity Tests, In Vitro](#) 87 and [Biological Reactivity Tests, In Vivo](#) 88 are designed to determine the biological reactivity of

mammalian cell cultures and the biological response of animals to elastomeric, plastic, and other polymer materials with direct or indirect patient contact. The biological reactivity of these materials may depend on both their surface characteristics and their extractable chemical components. The testing procedures set forth in these chapters can often be performed with the material or an extract of the material under test, unless otherwise specified.

#### Preparation of Extracts

Evaluation of the biocompatibility of a whole medical product is often not realistic; thus, the use of representative portions or extracts of selected materials may be the only practical alternative for performing the assays. When representative portions of the materials or extracts of the materials under test are used, it is important to consider that raw materials may undergo chemical changes during the manufacturing, processing, and sterilization of a medical product. Although *in vitro* testing of raw materials can serve as an important screening procedure, a final evaluation of the biocompatibility of a medical product is performed with portions of the finished and sterilized product.

The preparation of extracts is performed according to the procedures set forth under [Biological Reactivity Tests, In Vitro](#) (87) and under [Biological Reactivity Tests, In Vivo](#) (88). Extractions may be performed at various temperatures (121°, 70°, 50°, or 37°), for various time intervals (1 hour, 24 hours, or 72 hours), and in different extraction media. The choice of extraction medium for the procedures under [Biological Reactivity Tests, In Vitro](#) (87) includes Sodium Chloride Injection (0.9% NaCl) or tissue culture medium with or without serum. When medium with serum is used, the extraction temperature cannot exceed 37°. *In vivo* extraction medium includes the choices described under [Biological Reactivity Tests, In Vivo](#) (88) or the solvent to which the drug or medical device is exposed.

When choosing extraction conditions, select the temperature, solvent, and time variables that best mimic the "in use" conditions of the product. The performance of multiple tests at various conditions can be used to simulate variations in the "in use" conditions. Although careful selection of extraction conditions allows the simulation of manufacturing and processing conditions in the testing of raw materials, an evaluation of the biocompatibility of the product is performed with the finished and sterilized product.

#### In Vitro Testing

The procedures described under [Biological Reactivity Tests, In Vitro](#) (87) include an Agar Diffusion Test (indirect contact test), a Direct Contact Test, and an Elution Test (extraction test). The sample is biocompatible if the cell cultures do not exhibit greater than a mild reactivity (Grade 2) to the material under test, as described under [Biological Reactivity Tests, In Vitro](#) (87). The Agar Diffusion Test is designed to evaluate the biocompatibility of elastomeric materials. The material is placed on the agar overlay of the cell monolayer, which cushions the cells from physical damage by the material and allows leachable chemicals or materials to diffuse from the elastomer and contact the cell monolayer. Extracts of elastomeric materials are tested by placing the filter paper saturated with an extract of the elastomer on the solidified surface of the agar. The Direct Contact Test is designed for elastomeric or plastic materials that will not physically damage cells with which they are in direct contact. Any leachable chemicals diffuse from the material into the serum-supplemented growth medium and directly contact the cell monolayer. The Elution Test is designed to evaluate the extracts of polymeric materials. The material may be applied directly to the tissue culture media.

The performance of either the Agar Diffusion Test or the Direct Contact Test in combination with the Elution Test is the preferred testing protocol. Extraction of the product or materials for the Agar Diffusion Test or the Elution Test is performed as described in the Preparation of Extracts.

#### In Vivo Testing and Class Designation

According to the injection and implantation requirements specified in [Table 1](#) under [Biological Reactivity Tests, In Vivo](#) (88), plastics and other polymers are assigned a class designation between class I and class VI. To obtain a plastic or other polymer class designation, extracts of the test material are produced according to the specified procedures in various media. To evaluate biocompatibility, the extracts are injected systemically and intracutaneously into mice and rabbits. According to the specified injection requirements, a plastic or other polymer may initially be graded as class I, II, III, or V. If in addition to injection testing, implantation testing using the material itself is performed, the plastic or other polymer may be classified as class IV or class VI.

### BIOCOMPATIBILITY OF MEDICAL DEVICES AND IMPLANTS

In addition to evaluating medical products for compendial purposes according to the procedures specified under [Injections](#) (1), [Sterility](#) (71), [Biological Reactivity Tests, In Vitro](#) (87), [Biological Reactivity Tests, In Vivo](#) (88), [Transfusion and Infusion Assemblies and Similar Medical Devices](#) (161), [Elastomeric Closures for Injections](#) (381), and [Containers—Plastics](#) (661), medical devices and implants are evaluated for sensitization, subchronic toxicity, genotoxicity, hemocompatibility, chronic toxicity, carcinogenicity, reproductive or developmental toxicity, and biodegradation as required by the regulatory agencies.

The guidance provided by the regulatory agencies indicates that the extent of testing that is performed for a medical device or an implant depends on the following factors: (1) the similarity and uniqueness of the product relative to previously marketed ("predicate") products as considered in the Decision Flowchart; (2) the extent and duration of the contact between the product and the patient as described in the Categorization of Medical Devices; and (3) the material composition of the product as considered in the sections Decision Flowchart and In Vivo Testing and Class Designation.

#### Decision Flowchart

Guidance on comparing a medical device or an implant to previously marketed products is provided by the Biocompatibility Decision Flowchart (see [Figure 1](#)).

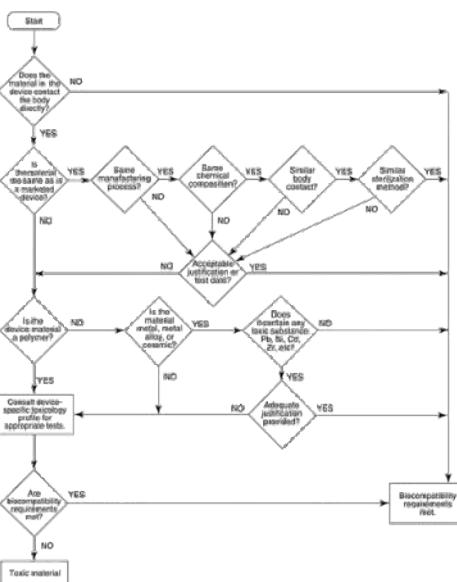

Fig. 1. Biocompatibility flowchart

as adapted from the FDA's Blue Book Memorandum #G95-1. The purpose of the flowchart is to determine whether the available data from previously marketed devices are sufficient to

...sure the safety of the device under consideration. As indicated by the flowchart, the material composition and the manufacturing techniques of a product are compared to those of the previously marketed products for the devices that come in direct contact with the body. In addition, the flowchart requires an evaluation of the toxicity of any unique material that has not been used in predicate devices. Responses to the questions posed in the flowchart lead to the conclusion that either the available data are sufficient or additional testing is required to ensure the safety of the product. When additional testing is required, guidance on the identification of appropriate testing procedures is provided in the section Test Selection Matrix.

#### Categorization of Medical Devices

To facilitate the identification of appropriate testing procedures, medical devices are divided and subdivided, as shown in [Table 2](#).

Table 2. Classification and Examples of Medical Devices

Device Category	Device Subcategory	Nature or Extent of Contact	Some Examples
	Skin	Devices that contact intact skin surfaces only	Electrodes, external prostheses, fixation tapes, compression bandages, and monitors of various types
Surface Devices	Mucosal Membrane	Devices communicating with intact mucosal membranes	Contact lenses, urinary catheters, intravaginal and intraintestinal devices (stomach tubes, sigmoidoscopes, colonoscopes, gas troscopes), endotracheal tubes, bronchoscopes, dental prostheses, orthodontic devices, and intrauterine devices
	Breached or Compromised Surfaces	Devices that contact breached or otherwise compromised body surfaces	Ulcer, burn, and granulation tissue dressings or healing devices and occlusive patches
	Blood Path, Indirect	Devices that contact the blood path at one point and serve as a conduit for entry into the vascular system	Solution administration sets, extension sets, transfer sets, and blood administration sets
External Communicating Devices	Tissue, Bone, or Dentin Communicating	Devices and materials communicating with tissue, bone, or pulp and dentin system	Laparoscopes, arthroscopes, draining systems, dental cements, dental filling materials, and skin staples
	Circulating blood	Devices that contact circulating blood	Intravascular catheters, temporary pacemaker electrodes, oxygenators, extracorporeal oxygenator tubing and accessories, dialyzers, dialysis tubing and accessories, hemoadsorbents, and immunoabsorbents
Implant Devices	Tissue or Bone	Devices principally contacting bone or principally contacting tissue and tissue fluid	Examples of the former are orthopedic pins, plates, replacement joints, bone prostheses, cements, and intraosseous devices; examples of the latter are pacemakers, drug supply devices, neuromuscular sensors and simulators, replacement tendons, breast implants, artificial larynxes, subperiosteal implants, and ligation clips
	Blood	Devices principally contacting blood	Pacemaker electrodes, artificial arteriovenous fistulae, heart valves, vascular grafts, internal drug delivery catheters, and ventricular-assist devices

according to the nature and extent of their contact with the body. Major categories of medical devices are surface devices, external communicating devices, and implant devices. These are then further subcategorized. Some examples of medical devices and implants belonging to each of the subcategories are also presented in [Table 2](#).

#### Test Selection Matrix

The matrix provides guidance on the identification of appropriate biological testing procedures for the three categories of medical devices: tests for Surface Devices (see [Table 3](#)), tests for External Communicating Devices (see [Table 4](#)), and tests for Implant Devices (see [Table 5](#)). Each category of devices is subcategorized and then even further subdivided according to the duration of the contact between the device and the body. The duration of contact is defined as (A) limited (less than 24 hours); (B) prolonged (24 hours to 30 days); or (C) permanent (more than 30 days). The biological effects that are included in the matrix are cytotoxicity, sensitization, irritation or intracutaneous reactivity, systemic toxicity, subchronic toxicity, genotoxicity, implantation, hemocompatibility, chronic toxicity, carcinogenicity, reproductive or developmental toxicity, and biodegradation. The general chapters that contain toxicity testing procedure for these biological effects are indicated in [Table 1](#).

Each subcategory in the matrix has an associated panel of testing requirements. Generally, the number of tests in the panel increases as the duration of the contact between the device and the body is extended and as the device or implant comes in closer contact with the circulatory system. Within several subcategories, the option of performing additional tests beyond those required should be considered on a case-by-case basis. Specific situations such as use of permanent implant devices or external communicating devices for pregnant women have to be taken into consideration in the manufacturer's decision to include reproductive or developmental testing. Guidance on the identification of possible additional testing procedures is provided in the matrix for each subcategory of medical devices.

#### GUIDANCE IN SELECTING THE PLASTIC OR OTHER POLYMER CLASS DESIGNATION FOR A MEDICAL DEVICE

To provide guidance on selecting the appropriate plastic or other polymer class designation for a medical device, each subcategory of Surface Devices (see [Figure 2](#))

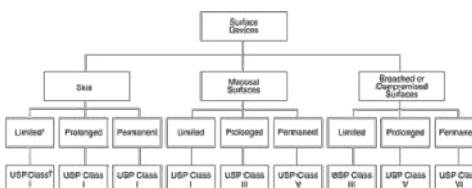

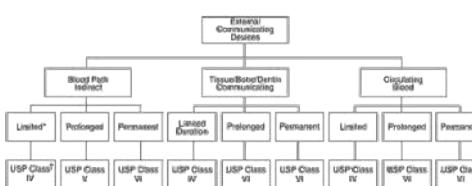

Fig. 2. USP plastic and other polymer class requirements for surface devices.\* Categorization based on duration of contact: limited—less than 24 hours; prolonged—24 hours to 30 days; permanent—more than 30 days.† USP Plastic Class designation.

and External Communicating Devices (see [Figure 3](#))

3. USP plastic and other polymer class requirements for external communicating devices. \* Categorization based on duration of contact: limited—less than 24 hours; prolonged—24 hours to 30 days; permanent—more than 30 days.† USP Plastic Class designation.

is assigned a USP Plastic Class designation (see [Biological Reactivity Tests, In Vivo](#) (88)). If the tests for each USP class designation are not sufficient for a specific device, the manufacturer or the practitioner must develop an appropriate set of tests. The indicated numerical class number increases relative to the duration (risk) of contact between the device and the body. In the category of Implant Devices, the exclusive use of class VI is mandatory. The assignment of USP Plastic Class designation is based on the test selection matrices illustrated in [Tables 3, 4, and 5](#).

The assignment of a plastic or other polymer class designation to a subcategory is not intended to restrict the use of higher classes of plastics or other polymers. Although the assigned class defines the lowest numerical class of plastic or other polymer that may be used in the corresponding device, the use of a numerically higher class of plastic is optional. When a device can be defined as belonging to more than one device category, the plastic or other polymer should meet the requirements of the highest numerical class.

### 1035 BIOLOGICAL INDICATORS FOR STERILIZATION

A biological indicator is broadly defined as a characterized preparation of a specific microorganism that provides a defined and stable resistance to a specific sterilization process. Microorganisms widely recognized as suitable for biological indicators are spore-forming bacteria, because, with the exception of ionizing radiation processes, these microorganisms are significantly more resistant than normal microflora. A biological indicator can be used to assist in the performance qualification of the sterilization equipment and in the development and establishment of a validated sterilization process for a particular article. Biological indicators are used in processes that render a product sterile in its final package or container, as well as for the sterilization of equipment, materials, and packaging components used in aseptic processing. Biological indicators may also be used to monitor established sterilization cycles and in periodic revalidation of sterilization processes. Biological indicators may also be used to evaluate the capability of processes used to decontaminate isolators or aseptic clean-room environments.

The principles and requirements for these applications are described under [Sterilization and Sterility Assurance of Compendial Articles](#) [1211](#).

#### TYPES OF BIOLOGICAL INDICATORS

There are at least three types of biological indicators. Each type of indicator incorporates a known species of a microorganism of known sterilization resistance to the sterilization mode. Some biological indicators may also contain two different species and concentrations of microorganisms.

One form of biological indicator includes spores that are added to a carrier (a disk or strip of filter paper, glass, plastic, or other materials) and packaged to maintain the integrity and viability of the inoculated carrier.

Carriers and primary packaging shall not contain any contamination (physical, chemical, or microbial) that would adversely affect the performance or the stability characteristics of the biological indicator. The carrier and primary packaging shall not be degraded by the specific sterilization process, which is used in a manner that will affect the performance of the biological indicator. The carrier should withstand transport in the primary and secondary packaging and handling at the point of use. The design of the carrier and primary packaging should minimize the loss of the original inoculum during transport, handling, and shelf life storage.

Another form of biological indicator is a spore suspension that is inoculated on or into representative units of the product to be sterilized. This represents an inoculated product; however, a simulated inoculated product may be used if it is not practical to inoculate the actual product. A simulated product is a preparation that differs in one or more ways from the actual product, but performs as the actual product using test conditions or during actual production sterilization processing. Spore suspensions with a known D value should be used to inoculate the actual or simulated product. If a simulated inoculated product is used, it must be demonstrated that it will not degrade the sterilization resistance of the biobinder. The physical design of actual or simulated product can affect the resistance of spore suspensions that are inoculated on or into the products. In the case of liquid inoculated products, it is often advisable to determine both the D value and z value of the specific biological indicator microorganism in the specific liquid product. The population, D value, z value where applicable, and endpoint kill time of the inoculated actual or simulated product should be determined.

A third form of biological indicator is a self-contained indicator. A self-contained biological indicator is designed so that the primary package, intended for incubation following sterilization processing, contains the growth medium for recovery of the process-exposed microorganisms. This form of biological indicator together with the self-contained growth medium can be considered a system. In the case of self-contained biological indicators, the entire system provides resistance to the sterilization process.

If the biological indicator is a paper strip or disk in a self-contained package that includes an available culture medium, the package design should be readily penetrable by the sterilizing agent. To allow for the time lag that may occur while the sterilizing agent reaches the contained microorganisms in the system, the D value, process endpoint kill time, and the survival time should be characterized for the system and not solely for the paper strip in the self-contained unit. Following the sterilizing treatment, the spore strip or disk is immersed in the self-contained medium by manipulation, which allows contact with the culture medium.

Self-contained biological indicators may also consist of a spore suspension in its own medium, and they often also contain a dye, which indicates positive or negative growth following incubation. Resistance of the self-contained system is dependent upon penetration of the sterilant into the package. Penetration may be controlled by the manufacturer through varying designs and composition of the self-contained biological indicator package, ampul, or container. Self-contained ampul biological indicators may be incubated directly following exposure to the sterilization process. The entire system is then incubated under the specified conditions. Growth or no growth of the treated spores is determined visually (either by observing a specified color change of an indicator incorporated in the medium or by turbidity) or by microscopic examination of the inoculated medium.

The self-contained system resistance characteristics must also comply with the labeling of the self-contained system and the relevant biological indicator monograph. The self-contained biological indicator system should withstand transport in the secondary packaging and handling at the point of use without breakage. The design of the self-contained system should be such to minimize the loss of the original inoculum of microorganisms during transport and handling. During or after the sterilization process, the materials used in the self-contained system shall not retain or release any substance that can inhibit the growth of low numbers of surviving indicator microorganism under culture conditions. Adequate steps must be taken to demonstrate that the recovery medium has retained its growth support characteristics after exposure to the sterilization process.

#### Preparation

All operations associated with the preparation of biological indicators are controlled by a documented quality system. Traceability is maintained for all materials and components incorporated in or coming into direct contact with the microorganism suspension, the inoculated carrier, or the biological indicator.

The preparation of stock spore suspensions of selected microorganisms used as biological indicators requires the development of appropriate procedures, including mass culturing, harvesting, purification, and maintenance of the spore suspensions. The stock suspension should contain predominantly dormant (nongerminating) spores that are held in a nonnutritive liquid.

The finished product (microbial suspension, inoculated carriers, or biological indicators) supplied by commercial manufacturers shall have no microorganisms, other than the test microorganism, present in sufficient numbers to adversely affect the product. The system to minimize the presence of microorganisms other than the biological indicator microorganism in the product will be validated, monitored, and recorded.

#### Selection for Specific Sterilization Processes

The selection of a biological indicator requires a knowledge of the resistance of the biological indicator system to the specific sterilization process. It must be established that the biological indicator system provides a challenge to the sterilization process that exceeds the challenge of the natural microbial burden in or on the product.

The effective use of biological indicators for the cycle development, process, and product validation, and routine production monitoring of a sterilization process requires a thorough knowledge of the product being sterilized, along with its component parts (materials and packaging). Only the widely recognized biological indicators specified in the particular biological indicator monograph should be used in the development or validation of a sterilization process. This will ensure that the biological indicator selected provides a greater challenge to the sterilization process than the bioburden in or on the product. Some users may require biological indicators with characteristics that differ from those widely available commercially. In such cases, users may grow their own spore cultures for the express purpose of preparing in-house biological indicators for their specific use. In such a case, the user is well advised to use organisms already described in the scientific literature as indicator organisms, and the user must have the capability of determining D and z values for in-house biological indicators. When biological indicators are prepared in-house, users must confirm the population, purity, and shelf life of the biological indicator to ensure the validity of any test conducted using the in-house biological indicator. When a bioburden-based sterilization process design is used, data comparing the resistance of the biological indicator to that of

bioburden are essential. Enumeration of the bioburden content of the articles being sterilized is also required. The process must result in a biologically verified lethality sufficient to achieve a probability of obtaining a nonsterile unit that is less than one in a million.

Alternatively, the overkill method may be used in the design of a sterilization process. In this case, specific assumptions are made regarding the resistance assumption used in establishing sterilization process lethality requirements. In general, all overkill processes are built upon the assumption that the bioburden is equal to one million organisms and that the organisms are highly resistant. Thus, to achieve the required probability of a nonsterile unit that is less than one in a million, a minimum 12 D process is required. A 12 D process is defined as a process that provides a lethality sufficient to result in a 12 log reduction, which is equivalent to 12 times a D value for organisms with sufficiently higher resistance than the

mean resistance of bioburden. Because the bioburden is assumed to be one million, an overkill process will result in a probability of nonsterility at much less than  $10^{-6}$  in actual practice. Overkill process design and evaluation may differ depending upon the sterilization process under test. The use of an overkill design and validation approach may minimize or obviate the need for bioburden enumeration and identification.

**Moist Heat**— For moist heat sterilization process, spores of suitable strains of *Bacillus stearothermophilus* are commercially available as biological indicators and frequently employed. Other heat-resistant spore-forming microorganisms such as *Clostridium sporogenes*, *Bacillus subtilis*, and *Bacillus coagulans* have also been used in the development and validation of moist heat sterilization processes.

**Dry Heat**— For dry heat sterilization, spores of *Bacillus subtilis* spp. are sometimes used to validate the process. During the validation of dry heat sterilization processes, endotoxin depyrogenation studies are frequently conducted in lieu of microbial inactivation studies during the establishment of sterilization cycles because the inactivation rate of endotoxin is slower than the inactivation rate of *Bacillus subtilis* spores. In practice the reduction of endotoxin titer by three or more logs will result in a process that also achieves a probability of nonsterility substantially lower than  $10^{-6}$ .

**Ionizing Radiation**— Spores of *Bacillus pumilus* have been used to monitor sterilization processes using ionizing radiation; however, this is a ceding practice. Radiation dose-setting methods that do not use biological indicators have been widely used to establish radiation processes. Furthermore, certain bioburden microorganisms can exhibit greater resistance to radiation than *Bacillus pumilus*.

**Ethylene Oxide**— For ethylene oxide sterilization, spores of a subspecies of *Bacillus subtilis* (*Bacillus subtilis* var. *niger*) are commonly used. The same biological indicator systems are generally used when 100% ethylene oxide or different ethylene oxide and carrier gas systems are used as sterilants.

**Vapor-Phase Hydrogen Peroxide (VPHP)**— This process has been shown to be an effective surface sterilant or decontaminant. VPHP is capable of achieving sterilization (probability of nonsterility of less than one in a million) when process conditions so dictate and if the target of sterilization is suitably configured. However, VPHP is also commonly used as a surface decontaminating agent in the treatment of sterility testing, biological and chemical containment, manufacturing isolators, and clean rooms.

Surface decontamination is a process that is distinct from sterilization of product contact materials, container-closure systems, or product. It is a process designed to render an environment free of detectable or recoverable microorganisms. Biological indicators are widely used to verify the efficacy of the decontamination process. However, in the case of decontamination, a spore log reduction value of three to four is adequate because the goal is decontamination rather than sterilization.

Table 1. Typical Characteristics for Commercially Supplied Biological Indicator Systems

Sterilization Mode	Example of a Typical D value (minutes)	Range of D values for Selecting a Suitable Biological Indicator (minutes)	Limits for a Suitable Resistance (depending on the particular D value [minutes])	
			Survival Time	Kill Time
Dry heat <sup>a</sup>	1.9	Min. 1.0	Min. 4.0	10.0
160°		Max. 3.0	Max. 14.0	32.0
Ethylene oxide <sup>b</sup>				
600 mg per liter	3.5	Min. 2.5	Min. 10.0	25.0
54°		Max. 5.8	Max. 27.0	68.0
60% relative humidity				
Moist Heat <sup>c</sup>	1.9	Min. 1.5	Min. 4.5	13.5
121°		Max. 3.0	Max. 14.0	32.0

a For  $1.0 \times 106$  to  $5.0 \times 106$  spores per carrier.

b For  $1.0 \times 106$  to  $5.0 \times 107$  spores per carrier.

c For  $1.0 \times 105$  to  $5.0 \times 106$  spores per carrier.

*Bacillus stearothermophilus* is the most prevalently used biological indicator for validating VPHP. Other microorganisms that may be useful as biological indicators in VPHP processes are spores of *Bacillus subtilis* and *Clostridium sporogenes*. Other microorganisms may be considered if their performance responses to VPHP are similar to those of the microorganisms cited above.

These spores may be inoculated on the surface of various gas-impermeable carrier systems having glass, metal, or plastic surfaces. Highly absorbent surfaces, such as fibrous substrates, or any other substrate that readily absorbs VPHP or moisture may adversely influence the VPHP concentration available for inactivation of inoculated microorganisms.

Paper substrates are not used because VPHP will degrade cellulose-based materials.

For representative characteristics of commercially supplied biological indicators, see Table 1.

The biological indicator may also be individually packaged in a suitable primary overwrap package that does not adversely affect the performance of the indicator, and is penetrable by VPHP. Spunbound polyolefin materials have proven to be well suited as an overwrap of biological indicators intended for use in evaluation of VPHP processes. The overwrap material may facilitate laboratory handling of the biological indicators following exposure to VPHP. Also, the use of an overwrap material to package VPHP biological indicators must be carefully assessed to ensure that, following VPHP exposure, residual hydrogen peroxide is not retained by the packaging material, possibly inducing bacteriostasis during the recovery steps. Microbial D values will be influenced by the presence of a biological indicator overwrap material relative to the rate of inactivation and the potential presence of residual VPHP. In cases where biological indicators (inoculated carriers) are being used without the primary package, stringent adherence to aseptic techniques is required.

#### PERFORMANCE EVALUATION

##### Manufacturer's Responsibility

The initial responsibility for determining and providing to the users the performance characteristics of a biological indicator<sup>1</sup> lot resides with the manufacturer of biological indicators. The manufacturer should provide with each lot of biological indicators a certificate of analysis that attests to the validity of biological indicator performance claims cited on the biological indicator package label or in the package insert of the label package. The manufacturer should define the sterilization process that the biological indicator will be used to evaluate. The characterization of each type of biological indicator, which provides the basis for label claims, should be performed initially by the manufacturer of the biological indicator using specialized and standardized apparatus under precisely defined conditions.<sup>1</sup> The manufacturer should also provide information concerning the D value, the method by which the D value was determined, and microbial count and resistance stability of the biological indicator throughout the labeled shelf life of the indicator. Optimum storage conditions should be provided by the manufacturer, including temperature, relative humidity, and any other requirements for controlled storage. The data obtained from the various required performance assays should be cited in a package insert or on the label of the biological indicator package. The manufacturer should provide directions for use, including the medium and conditions to be used for the recovery of microorganisms after exposure to the sterilization process. Disposal instructions should also be provided by the manufacturer of the biological indicator.

#### User's Responsibility

Commercial Product— When biological indicators are purchased from a commercial source, their suitability for use in a specific sterilization process should be established through developmental sterilization studies unless existing data are available to support their use in the process. The user should establish in-house acceptance standards for biological indicator lots and consider rejection in the event the biological indicator lot does not meet the established in-house performance standards. A Certificate of Performance should be obtained for each lot of indicators, and the user should routinely perform audits of the manufacturer's facilities and procedures. If certificates are not obtained and audits have not been performed, or if the biological indicators are to be used outside of the manufacturer's label claims, verification and documentation of performance under conditions of use must exist.

Upon initial receipt of the biological indicator from a commercial supplier, the user should verify the purity and morphology of the purchased biological indicator microorganisms.

Verification of at least the proper genus is desirable. Also, a microbial count to determine the mean count per biological indicator unit should be conducted. The manufacturer's comments relative to D value range, storage conditions, expiration dating, and stability of the biological indicator should be observed and noted. The user may consider conducting a D value assessment before acceptance of the lot. Laboratories that have the capability of performing D value assays could conduct a D value determination using one of the three methods cited in the general test chapter [Biological Indicators—Resistance Performance Tests](#) <sup>1</sup> and in the appropriate USP monographs for specific biological indicators.

Particularly important is the verification of the D value and count stability of the biological indicator system if long-term storage is employed.

In the event the spore crop is maintained for longer than 12 months under documented storage conditions, both spore count and resistance analysis must be conducted, unless performance of an original parent crop has been validated for a longer storage period. The result of spore count and resistance assays should be within the range of acceptability established during initial acceptance of the spore crop lot.

Noncommercial Product— A user of biological indicator systems may elect to propagate microorganisms for developing in-house biological indicators to develop or validate sterilization processes. In the event a user becomes a "manufacturer" of biological indicators, biological indicator performance requirements must be met. If the biological indicator system is used for the development of new sterilization processes or validation of existing processes, the same performance criteria described for commercial manufacturers of biological indicators must be followed.

#### Spore Crop Preparation

Because most biological indicators use microbial spores, accurate records of spore crop identification must be maintained by commercial and noncommercial biological indicator manufacturers. These records should include records pertaining to the source of the initial culture, identification, traceability to the parent spore crop, subculture frequency, media used for sporulation, changes in media preparation, any observation of crop contamination, and pre- and post-heat shock data. Records of usage of the spore crop and resistance to sterilization (namely, D values and z values where applicable) should also be maintained.

#### Instrumentation

The instrumentation used to evaluate the sterilization resistance of spore crops must be consistent with existing standards<sup>2</sup> related to the performance evaluation of biological indicator systems.

Equipment for the determination of D values of microorganisms exposed to VPHP should be able to closely control equipment operating parameters as described for other biological indicator systems under [Biological Indicators—Resistance Performance Tests](#) <sup>1</sup>. Particularly important is the assurance of a consistently reproducible VPHP concentration, delivered within a finite time, and maintained within a specified concentration range or VPHP pressure range for a defined increment of time. Introduction of biological indicators into a stabilized concentration of VPHP conditions should be via a system that permits rapid entry and removal of the test units from the chamber. Also, the design of the test chamber should allow for the attainment of steady-state VPHP concentrations and pressure, or the use of a defined amount of cubic feet of free flowing VPHP at a standardized pressure and temperature. Currently, VPHP concentration measurement devices may not be widely used. Therefore, exposure conditions may need to be based on the maintenance of steady-state VPHP pressures or flow rates resulting from a known initial weight of hydrogen peroxide, admitted to the chamber in a defined unit of time. Using this information, together with the known fixed volume of the chamber environment, a calculation of the approximate VPHP concentration can be made. If conditions are maintained constant throughout each D value assessment run, comparisons of relative resistance among different biological indicator lots may be readily determined.

#### USE FOR IN-PROCESS VALIDATION

Regardless of the mode of sterilization, the amount of the initial population of the microorganisms, its resistance to sterilization, and the site of inoculation on or in the product can all influence the rate of biological indicator inactivation.

During product microbial challenges, various areas of the product should be inoculated with biological indicators. If, for example, a container with a closure system is sterilized, both the product solution and the closure should be challenged to ensure that sterilization equivalent to a 10<sup>-6</sup> (one in a million probability of a nonsterile unit) sterilization assurance level (SAL) will be obtained in the solution as well as at the closure site.

One may need to determine through laboratory studies whether product components are more difficult to sterilize than, for example, a solution or drug within the product. Depending on the locations of the product components most difficult to sterilize, different process parameters may be involved in assuring microbial inactivation to an SAL of 10<sup>-6</sup>. The product performance qualification phase should identify the most important process parameters for inactivation of microorganisms at the sites most difficult to sterilize. Once these critical processing parameters are determined, during sterilization in-process validation of the product, they should be operated at conditions less than the conditions stated in the sterilization process specifications. Biological indicator survival is predicated upon both resistance and population. Therefore, a 106 biological indicator population is not always required to demonstrate a 10<sup>-6</sup> SAL. The appropriate use for biological indicators is to employ them to confirm that the developed process parameters result in the desired SAL. In moist heat sterilization, the biological indicator is used to establish that physically measured lethality can be verified biologically. Biological indicators with substantive D values and populations substantially less than 106 are adequate to validate many sterilization and decontamination processes. It is important that the users be able to scientifically justify their selection of a biological indicator.

1 See Apparatus under [Biological Indicators—Resistance Performance Tests](#) <sup>1</sup>. These apparatuses have been designed to provide consistent physical conditions applicable to the characterization of biological indicators. The required performance characteristics are also indicated.

USP32-NF27 Page 416

Pharmacopeial Forum: Volume No. 27(4) Page 2820

1041 BIOLOGICS

Products such as antitoxins, antivenins, blood, blood derivatives, immune serums, immunologic diagnostic aids, toxoids, vaccines, and related articles that are produced under license in accordance with the terms of the federal Public Health Service Act (58 Stat. 682) approved July 1, 1944, as amended, have long been known as "biologics." However, in Table III, Part F, of the Act, the term "biological products" is applied to the group of licensed products as a whole. For Pharmacopeial purposes, the term "biologics" refers to those products that must be licensed under the Act and comply with Food and Drug Regulations—Code of Federal Regulations, Title 21 Parts 600-680, pertaining to federal control of these products (other than certain diagnostic aids), as administered by the Center for Biologics Evaluation and Research or, in the case of the relevant diagnostic aids, by the Center for Devices and Radiological Health of the federal Food and Drug Administration.

Each lot of a licensed biologic is approved for distribution when it has been determined that the lot meets the specific control requirements for that product as set forth by the Office. Licensing includes approval of a specific series of production steps and in-process control tests as well as end-product specifications that must be met on a lot-by-lot basis. These can be altered only upon approval by the Center for Biologics Evaluation and Research and with the support of appropriate data demonstrating that the change will yield a final product having equal or superior safety, purity, potency, and efficacy. No lot of any licensed biological product is to be distributed by the manufacturer prior to the completion of the specified tests. Provisions generally applicable to biologic products include tests for potency, general safety, sterility, purity, water (residual moisture), pyrogens, identity, and constituent materials (Sections 610.10 to 610.15 and see Safety Tests—Biologics under [Biological Reactivity Tests, In Vivo](#) (88), [Sterility Tests](#) (71), [Water Determination](#) (921), and [Pyrogen Test](#) (151), as well as [Bacterial Endotoxins Test](#) (85)). Constituent materials include ingredients, preservatives, diluents and adjuvants (which generally should meet compendial standards), extraneous protein in cell-culture produced vaccines (which, if other than serum-originating, is excluded) and antibiotics other than penicillin added to the production substrate of viral vaccines (for which compendial monographs on antibiotics and antibiotic substances are available). Additional specific safety tests are also required to be performed on live vaccines and certain other items. Where standard preparations are made available by the Center for Biologics Evaluation and Research (Section 610.20), such preparations are specified for comparison in potency or virulence testing. The U.S. Opacity Standard is used in estimating the bacterial concentration of certain bacterial vaccines and/or evaluating challenge cultures used in tests of them. (See also Units of Potency in the General Notices.)

The Pharmacopeial monographs conform to the Food and Drug Regulations in covering those aspects of identity, quality, purity, potency, and packaging and storage that are of particular interest to pharmacists and physicians responsible for the purchase, storage, and use of biologics. Revisions of the federal requirements affecting the USP monographs will be made the subjects of USP Supplements as promptly as practicable.

**Vehicles and Added Substances**— Vehicles and added substances suitable for biologics are those named in the Food and Drug Regulations.

**Containers for Injections**— Containers for biologics intended to be administered by injection meet the requirements for Containers for Injections under [Injections](#) (1).

**Volume in Container**— The volumes in containers of biologics intended to be administered by injection meet the requirements for Volume in Container under [Injections](#) (1).

**Labeling**— Biologics intended to be administered by injection comply with the requirements for Labeling under [Injections](#) (1). In addition, the label on the final container for each biologic states the following: the title or proper name (the name under which the product is licensed under the Public Health Service Act); the name, address, and license number of the manufacturer; the lot number; the expiration date; and the recommended individual dose for multiple-dose containers. The package label includes all of the above, with the addition of the following: the preservative used and its amount; the number of containers, if more than one; the amount of product in the container; the recommended storage temperature; a statement, if necessary, that freezing is to be avoided; and such other information as the Food and Drug regulations may require.

**Packaging and Storage**— The labeling gives the recommended storage temperature (see General Notices). Precautions should be taken where products labeled to be stored at a temperature between 2° and 8° are stored in a refrigerator, in order to assure that they will not be frozen. Diluents packaged with biologics should not be frozen. Some products (as defined in Section 600.15) are to be maintained during shipment at specified temperatures.

**Expiration Date**— For compendial articles the expiration date identifies the time during which the article may be expected to meet the requirements of the Pharmacopeial monograph, provided it is kept under the prescribed storage conditions. This date limits the time during which the product may be dispensed or used (see General Notices, page 1). However, for biological products, the stated date on each lot determines the dating period, which begins on the date of manufacture (Section 610.50) and beyond which the product cannot be expected beyond reasonable doubt to yield its specific results and to retain the required safety, purity, and potency (Section 300.3 (1) and (m)). Such a dating period may comprise an in-house storage period during which it is permitted to be held under prescribed conditions in the manufacturer's storage, followed by a period after issue therefrom. The individual monographs usually indicate both the latter period and (in parentheses) the permissible in-house storage period. If the product is held in the manufacturer's storage for a longer period than that indicated (in parentheses), the expiration date is set so as to reduce the dating period after issue from the manufacturer's storage by a corresponding amount.

**Auxiliary Information**— Please [check for your question in the FAQs](#) before contacting USP.

## 1043 ANCILLARY MATERIALS FOR CELL, GENE, AND TISSUE-ENGINEERED PRODUCTS

### INTRODUCTION

A wide variety of reagents and materials, many of which are unique or complex, are required for the manufacture of cell, gene, and tissue-engineered products. These materials include plasma- or serum-derived products, biological extracts, antibiotics, cytokines, culture media, antibodies, polymeric matrices, separation devices, density gradient media, toxins, conditioned media supplied by "feeder cell layers", fine chemicals, enzymes, and processing buffers. Many of these items are used to ensure the survival and promote the growth of certain cell populations, although their mechanism of action may not be entirely understood. Examples include fetal bovine serum (FBS) and various media supplements. Other items, such as highly purified cholera toxin, are introduced into the processing stream during manufacturing to exert a specific biochemical effect and are immediately washed out in subsequent processing steps to avoid unwanted toxicity at a later point. The finished biological products produced in such processes are often complex mixtures that, in some cases, cannot be completely characterized. Careful scrutiny of the materials used in manufacturing is necessary to prevent the introduction of adventitious agents or toxic impurities, as well as to ensure the ultimate safety, effectiveness, and consistency of the final product.

In cell, gene, and tissue-engineered product manufacturing, these reagents and materials are collectively called ancillary materials (AMs). AMs have also been referred to as ancillary products, ancillary reagents, processing aids, and process reagents. AMs were first discussed under the synonym ancillary products in the U.S. Food and Drug Administration Notice, "Application of Current Statutory Authorities to Human Somatic Cell Therapy Products and Gene Therapy Products" (Federal Register 58(197), October 14, 1993, pp. 53248–53251). This document established the FDA's authority to regulate human somatic cell therapy products and gene therapy products. AMs are also synonymous with "processing materials" that were defined in 21 CFR Part 1271, "Current Good Tissue Practice for Manufacturers of Human Cellular and Tissue-Based Products; Inspection and Enforcement; Proposed Rule" (Federal Register 66(5), January 8, 2001, pp. 1508–1559). AMs can be analogous to "components", and in some cases, "containers" as described in the current good manufacturing practice (cGMP) regulations for finished pharmaceuticals as outlined in 21 CFR 211.80 through 211.94 and 211.101(b) and (c).

The defining property of AMs is that they are not intended to be present in the final product. They are materials used as processing and purification aids or agents that exert their effect on the therapeutic substance. Materials or components that are intended to be in the final product dosage form (e.g., genetic materials, biopolymeric supports, physiological buffers) are not AMs. Cell banks and virus banks are also not considered AMs; there are a number of guidances that describe requirements for their certification. However "helper" viruses and "helper" plasmids may be considered AMs when they are not intended to be part of the final product.

The quality of an AM can affect the stability, safety, potency, and purity of a cell, gene, or tissue-engineered product. For example, the mechanism by which an AM exerts its effect may not be known, and the impact of normal variation of the AM on the quality and safety of the therapeutic product may not be understood. Alternatively, AMs of human or animal origin may present an infectious disease transmission risk. Other AMs, if administered to humans, may cause an immune reaction. Finally, an AM with toxic properties that is introduced into a manufacturing process and is not adequately removed in subsequent processing steps will expose the patient to a toxic substance and may impair the effectiveness of the

therapeutic entity. These risks to the quality and safety of the therapeutic product are often heightened with cell, gene, and tissue-engineered products, due to the limited ability to conduct extensive in-process and release tests. For example, lack of in-process holding steps or limited shelf life may create the need to administer the cell, gene, or tissue-engineered products before in-process or final-release testing results are available. In other cases, the scarcity of suitable donor tissue or the complex logistics in the transport of biological materials may limit the amount of material available for testing. To minimize these risks, whenever possible, it is necessary to implement rigorous material qualification and prudent application of manufacturing process controls.

Frequently, these novel therapeutic products are created using complicated biological processes. The AMs employed in these procedures may be selected primarily for their unique functional contributions or biological effects. Whenever possible, it is preferable to source AMs that are approved or licensed therapeutic products because they are well characterized, have an established toxicological profile, and are manufactured according to controlled and documented procedures. Conversely, the AM may be intended "for research use" and may, therefore, lack the level of qualification necessary for use in the production of a therapeutic product. In either case, the manufacturer of the cell, gene, or tissue-engineered product should develop comprehensive and scientifically sound qualification plans to ensure the traceability, consistency, suitability, purity, and safety of the AM. In cases where AMs are products approved for use for therapeutic purposes, the level of qualification will probably be less extensive than that for a material intended for research purposes. However, their suitability in the manufacturing process will still need to be established when the AM is being used beyond the scope of its intended use or labeling. The purpose of this chapter is to provide guidance in developing appropriate qualification programs for AMs employed in cell, gene, and tissue-engineered product manufacturing.

#### QUALIFICATION OF ANCILLARY MATERIALS

Qualification is the process of acquiring and evaluating data to establish the source, identity, purity, biological safety, and overall suitability of a specific AM. The responsibility for AM qualification resides with the developer or manufacturer of the cell, gene, or tissue-engineered product. This section outlines the basis by which a manufacturer can establish rational and scientifically sound programs for qualifying AMs, although the broad nature of the cell, gene, and tissue-engineered products and of the AM used to produce these products make it difficult to recommend specific tests or protocols for a qualification program. Thorough documentation is the cornerstone of any qualification program.

A well-designed qualification program becomes more comprehensive as product development progresses. In the early stages of product development, safety is the primary focus. In the later stages, AM production and qualification activities should be comprehensively developed to support eventual licensure of the cell, gene, and tissue-engineered product. On some occasions, complex or unique substances that have been shown to be essential for process control or production may not be available from suppliers that produce them in compliance with cGMP. In these situations, the manufacturer will have to develop a scientifically sound strategy for qualification. A qualification program for AMs used in cell, gene, and tissue-engineered product manufacturing should address each of the following areas: (1) identification, (2) selection and suitability for use in manufacturing, (3) characterization, (4) vendor qualification, and (5) quality assurance and control.

##### Identification

The first step in any qualification program is the listing of all of the AMs used in a given product manufacturing and where in the manufacturing process they are to be employed. The source and intended use for each material should be established, and the necessary quantity or concentration of each material should be determined. Also, alternate sources for each material should be identified.

##### Selection and Suitability for Use

Developers of cell, gene, and tissue-engineered products should establish and document selection criteria for AMs and qualification criteria for each vendor early in the design phase of product development. Selection criteria should include assessments of microbiological and chemical purity, identity, and biological activity pertinent to the specific manufacturing process. It is important to address these issues early in product development because certain AMs that are initially considered necessary may be impossible or prohibitively expensive to qualify, thereby justifying the investigation of alternatives or replacements. Examples include some animal- or human-derived materials that in some cases have alternate (i.e., plant or chemically synthesized) sources.

AMs of animal or human origin should be selected cautiously due to the potential infectious or zoonotic disease risks associated with these materials. Vendors should be selected that can supply documentation regarding the country of origin for animal-derived AMs to address concerns regarding transmissible spongiform encephalopathies and other diseases of agricultural concern, like tuberculosis and brucellosis. In many cases, the chain of custody for animal-derived AMs (i.e., abattoir → intermediate processing center → final processing center) will need to be documented. Vendors of human-derived AMs should be able to supply documentation regarding material traceability. For instance, human plasma-derived AMs should be sourced from licensed facilities that control the donor pool and appropriately screen the individual donors for relevant human infectious diseases. In some cases, vendors of animal- and human-derived AMs supply different grades of materials, some of which will be more suitable for use in cell, gene, and tissue-engineered product manufacturing than other grades. For example, FBS can be obtained that has been processed to reduce the risk of bovine viral contamination by subjecting it to validated irradiation and nanofiltration processes. Also, many animal and human plasma-derived components are subjected to chemical (detergent or solvent treatment) or physical (heat exposure for extended periods of time) treatments that have been shown through validation studies to significantly reduce the risk of adventitious microbial or viral contamination associated with starting AMs. Such AMs are preferred for use in cell, gene, and tissue-engineered product manufacturing processes because they significantly reduce the risks associated with the original material.

The complexity of risk assessment can be reduced by employing one of a number of quantitative or semiquantitative approaches, such as failure mode effects analysis (FMEA), quality function deployment (QFD), or hazard analysis and critical control point (HACCP). These programs typically assign a point value to each risk parameter for an AM that results in cumulative scores that make it easier to prioritize effort and resources for decreasing the risks associated with AMs. For example, an AM that has a strong safety profile and is used in minimal amounts in upstream steps of the manufacturing process and is thoroughly washed from the system would accumulate a low point score. Conversely, an AM that is known to be toxic and is employed in downstream processing would, therefore, possess a higher potential for appearing as a residual in the final product and would be assigned a higher point value. One can also assign points based on the risk classification (see Risk Classification).

##### Characterization

Specific quality control characterization tests need to be developed or adopted and implemented for each AM. The set of tests for each AM should assess a variety of quality attributes, including identity, purity, functionality, and freedom from microbial or viral contamination. The appropriate level of testing for each AM is derived from its risk assessment profile and the knowledge gained during development. Test specifications should be developed for each AM to ensure consistency and performance of the manufacturing process. Acceptance criteria should be established and justified on the basis of the data obtained from lots used in preclinical and early clinical studies, lots used for demonstration of manufacturing consistency, and relevant development data, such as those arising from analytical procedure development and stability studies.

Some AMs that are biological in nature may be difficult to fully characterize. Because these materials exert their effects through complex biological activities, and biochemical testing may not be predictive of the AM's process performance, functional or performance testing may be needed. Performance variability of such materials may have a detrimental impact on the potency and consistency of the final therapeutic product. Examples of complex functionality testing for AMs include growth promotion testing of individual lots of FBS on the cell line used in manufacturing, performance testing of digestive enzyme preparations, and in vitro tissue culture cytotoxicity assays. (see aspects of Performance Testing).

##### Vendor Qualification

Vendors supplying AMs should be qualified at the earliest opportunity. An early audit of the vendor's manufacturing facility, including their GMP and AM testing program, are basic elements of a vendor qualification program. A review of the vendor's processing procedures and documentation program is essential in establishing confidence in the vendor as a reliable supplier. Additionally, vendors that have been certified through an ISO inspection program or audited by other governmental agencies tend to have robust quality systems in place. Reports of past audits of U.S. suppliers obtained through the Freedom of Information (FOI) Act may augment the qualification process.

It is important to develop a good working relationship with a vendor. In some cases, the vendor may provide higher manufacturing standards, custom formulation services, or replacement of substandard components upon request, with or without additional costs. A good rapport is essential if further investigation into AM suppliers is warranted. It is also critical to ensure that the vendor takes appropriate steps to prevent cross contamination between its products during manufacture. Vendors should be familiar with the principles of validation, especially cleaning validation, as well as viral inactivation and sterilization validation. Finally, systems should be established where vendors supply written certification of processing or sourcing changes to customers, well in advance of the implementation of the changes so that customers can evaluate the potential impact of such changes.

##### Quality Control and Quality Assurance

Because the components of the qualification program are multifaceted and need to be in compliance with cGMP, they should be monitored by a quality assurance/quality control unit (QAU). Typical QAU activities include the following systems or programs: (1) incoming receipt, segregation, inspection, and release of materials prior to use in manufacturing, (2) vendor auditing and certification, (3) certificate of analysis verification testing, (4) formal procedures and policies for out-of-specification materials, (5) stability testing, and (6) archival sample storage.

#### RISK CLASSIFICATION

A scientifically sound and rational qualification program should be designed for each AM and should take into account the source and processes employed in its manufacture. Whenever available, AMs that are approved or licensed therapeutic products are preferable because they are well-characterized with an established toxicological profile and are manufactured according to controlled and documented procedures. Licensed biologics, approved drugs, and approved or cleared medical devices or implantable materials that have been incorporated into cell, gene, or tissue-engineered product manufacturing processes present a known or more favorable safety profile for the patient than nonapproved or nonlicensed versions. Qualification programs for these AMs should reflect the extensive scrutiny that these items were subjected to in their development and manufacture. Consequently, greater emphasis should be placed on the investigation of the impact of inherent variability of these AMs on final product function. For instance, a manufacturer may utilize human serum albumin, intended for human administration, as a supplement to a cell cultivation medium for a cell-based product. Because the cell-based product is marketed as a licensed biological, one need not repeat all the testing already performed by the supplier as part of material qualification. In contrast, the impact of lot-to-lot variability on cell growth rate or maintenance of an important differentiated cellular property may be a prudent area of investigation. Alternatively, the stability of this material at the concentration employed in processing or its potential for interaction with other processing components may also be areas worthy of investigation. Such approaches to AM qualification therefore focus on the AM as a potential source of variability that may influence final product potency and safety. Qualification programs for these AMs should be comprehensive to minimize consumer risk and ensure that unacceptable lots or adulteration will be detected.

The qualification program must also take into account the quantity of the AM employed in manufacturing as well as its point of introduction in the manufacturing process. A relevant example is the use of FBS as a supplement to a tissue culture medium used to expand a stem cell population from a specific tissue for eventual administration to a patient (see Manufacturing Overview under [Cell and Gene Therapy Products \(1046\)](#)). A qualification program for such an AM would include (a) assurance that the serum was sourced from a country or region known to be free of bovine spongiform encephalopathy (BSE); (b) assurance that the source herds are monitored and test negative for specific diseases relevant in agricultural settings (e.g., tuberculosis, brucellosis, foot and mouth disease); (c) testing of the serum for sterility, mycoplasma, endotoxin content, and adventitious bovine viruses known to be associated with the material; <sup>1</sup> (d) the review and archiving of the supplier's certificate of analysis; (e) lot-to-lot assessment of the ability of the serum to consistently expand a representative cell population using a standardized cell culture quality control assay; and (f) on-site audit of the supplier to ensure that the material is sourced and processed in a manner deemed acceptable by a responsible QA unit.

To aid manufacturers and developers in the design of their qualification programs for a variety of AMs, tiers of sample risk categories are presented in [Tables 1–4](#) and are provided as a guide. Risk is also dependent on the amount and the stage at which the AM is used in the manufacturing process. [Tables 1–4](#) do not address the impact of quantity or stage of use.

**Tier 1**—These AMs are low-risk, highly qualified materials that are well-suited for use in manufacturing. The AM is either a licensed biologic, an approved drug, an approved or cleared medical device, or it is intended for use as an implantable biomaterial. Generally these components or materials are obtained as a sterile packaging system or dosage form intended for their label use, but are instead utilized "off label" in the manufacturing process for the cell, gene, or tissue-engineered product.

**Tier 2**—These AMs are low-risk, well-characterized material that are well-suited for use in manufacturing. Their intended use is for drug, biologic, or medical device manufacture, including cell, gene, and tissue-engineered products as AMs, and they are produced under relevant cGMPs. Most animal-derived materials are excluded from this category.

**Tier 3**—These AMs are a moderate risk material that will require a higher level of qualification than previous tier materials. Frequently, these materials are produced for in vitro diagnostic use and are not intended for use in the production of cell, gene, or tissue-engineered products. In some cases, upgrade of AM manufacturing processes may be necessary in order to employ the AM in manufacturing of these products (e.g., modification of the production process for a diagnostic grade monoclonal antibody to include robust viral removal steps in purification).

**Tier 4**—This is the highest risk level for AMs. Extensive qualification is necessary prior to use in manufacturing. The material is not produced in compliance with cGMPs. AMs are not intended for use in the production of cell, gene, or tissue-engineered products. This risk level includes highly toxic substances with known biological mechanisms of action, and also includes most complex, animal-derived fluid materials not subjected to adventitious viral removal or inactivation procedures. These materials may require (a) an upgrade of AM manufacturing processes; (b) treatment of AMs to inactivate or remove adventitious agents, disease-causing substances, or specific contaminants (e.g., animal viruses, prions); (c) testing of each lot of material to ensure that it is free of adventitious agents, disease-causing substances, or specific contaminants; (d) validation of the manufacturing process of the cell, gene, or tissue-engineered product to assess consistency of removal of a known toxic substance or lot-release testing to demonstrate reduction levels considered to be safe; or (e) validation of the manufacturing process of the cell, gene, or tissue-engineered product to assess consistency of removal or inactivation of adventitious agents, disease-causing substances, or specific contaminants associated with the material. Developers in the early stages of development should evaluate the necessity of these materials and explore alternative substances or sources.

Table 1. AM Risk Tier 1

Low-Risk, Highly Qualified Materials with Intended Use as Therapeutic Drug or Biologic, Medical Device, or Implantable Material

Example	Typical Use in Cell, Gene, or Tissue-Engineered Product Manufacturing	Qualification or Risk Reduction Activities
Recombinant insulin for injection	Cell culture medium additive	<ul style="list-style-type: none"> <li>• DMF cross reference (when possible or practical)</li> <li>• Certificate of analysis</li> <li>• Assess lot-to-lot effect on process performance<sup>1</sup></li> <li>• Assess removal from final product</li> <li>• Stability assessment on AM as stored for use in manufacturing<sup>2</sup></li> </ul>
Organ preservation fluid	Process biological fluid employed in tissue transport or processing	
Human serum albumin for injection	Cell culture medium	
Sterile fluids for injection	Process biological fluid employed in tissue transport, cell processing, purification	
Implantable biomaterials (formed collagen, silicone, polyurethane constructs intended for surgical implantation)	Scaffolds, matrices for immobilized cellular cultivation	
Recombinant deoxyribonuclease for inhalation or injection	Process enzyme employed in viral vector manufacturing, stem cell processing	
Antibiotics for injection <sup>3</sup>	Cell culture medium and biopsy transport fluid additive to reduce risk of bacterial contamination	
Injectable monoclonal antibodies	Immunologically targeting specific cell populations for selection or removal	
Injectable cytokines	Cell culture medium	
Vitamins for injection; defined nutrients, chemicals, or excipients intended for injection	Cell culture medium additive employed in cell expansion, controlled cellular differentiation/activation step, or manufacture of a viral vector	
IV bags, transfer sets and tubing, cryopreservation bags, syringes, needles	Storage vessels or container closure systems, closed aseptic transfer systems	

<sup>1</sup> See Performance Testing.

<sup>2</sup> Often AMs are aliquoted or stored at different concentrations, in different buffers, or under conditions that are different from those stated on the label or previously validated. Data

should be generated that demonstrate the stability and preservation of activity of the AM under the conditions that are specific to the manufacturing application.

3 Beta lactam antibiotics should not be used as AMs due to the risk of patient hypersensitivity.

Table 2. AM Risk Tier 2  
Low-Risk, Well Characterized Materials with Intended Use as AMs, Produced in Compliance with GMPs

Example	Typical Use in Cell, Gene, or Tissue-Engineered Product Manufacturing	Qualification or Risk Reduction Activities
Recombinant growth factors, cytokines <sup>1</sup>	Cell culture medium additive	
Immunomagnetic beads	Immunomagnetic separation of cells	
Human AB serum	Cell culture medium additive	
Progesterone, estrogen, vitamins, purified chemicals (USP-grade)	Cell culture medium additives, induction agents, buffer components	
Sterile process buffers	Process biological fluid employed in tissue transport, cell processing, purification	
Biocompatible polymers, scaffolds, hydrogels	Scaffolds, matrices for immobilized cellular cultivation	
Proteolytic enzymes	Process enzyme	
Tissue culture media	Cell culture medium additive	
Monoclonal antibodies	Immunologically targeting specific cell populations for selection or removal	
Density gradient media	Cell separation via centrifugation	

1 These AMs should be produced from nonmammalian, recombinant sources (i.e., microbially grown in the absence of animal-derived growth medium components).

2 See Performance Testing.

3 Often AMs are aliquoted or stored at different concentrations, in different buffers, or under conditions that are different from those stated on the label or previously validated. Data should be generated that demonstrates the stability and preservation or activity of the AMs under the conditions that are specific to the manufacturing application.

Table 3. AM Risk Tier 3  
Moderate-Risk Materials Not Intended for Use as AMs  
(frequently produced for in vitro diagnostic use or reagent grade materials)

Example	Typical Use in Cell, Gene, or Tissue-Engineered Product Manufacturing	Qualification or Risk Reduction Activities
Recombinant growth factors, cytokines	Cell culture medium additive	
Tissue culture media	Cell culture medium additive	
Monoclonal antibodies (diagnostic-grade produced in cell culture)	Immunologically targeting specific cell populations for selection or removal	
Process buffers	Process biological fluid employed in tissue transport, cell processing, purification	
Novel polymers, scaffolds, hydrogels	Scaffolds, matrices for immobilized cellular cultivation	
Proteolytic enzymes	Process enzyme	
Purified chemicals (reagent-grade)	Culture medium additives, induction agents, buffer components	

1 See Performance Testing.

2 Often AMs are aliquoted or stored at different concentrations, in different buffers, or under conditions that are different from those stated on the label or previously validated. Data should be generated that demonstrates the stability and preservation or activity of the AM under the conditions that are specific to the manufacturing application.

Table 4. AM Risk Tier 4  
High-Risk Materials

Example	Typical Use in Cell, Gene, or Tissue-Engineered Product	Qualification or Risk Reduction Activities
FBS	Cell culture medium additive	
Animal-derived (including human) extracts	Cell culture medium additive	
Animal-derived polymers, scaffolds, hydrogels	Scaffolds, matrices for immobilized cellular cultivation	
Purified enzymes	Process enzyme	
Ascites-derived antibodies or proteins	Immunologically targeting specific cell populations for selection or removal	
Animal or human cells used as feeder layers	Cell culture substratum or source of medium components	
Chemical entities with known toxicities (i.e. methotrexate, cholera toxin, Staphylococcus aureus pore-forming hemolysin, Staphylococcus enterotoxins A and B, toxic shock syndrome toxin)	Selection agents used in cell culture to improve or maintain transgene expression, enhance cellular proliferation, improve cell survival upon cryopreservation, superantigens for the activation of T cells	<ul style="list-style-type: none"> <li>Same as in <a href="#">Table 3</a>, plus</li> <li>Verify traceability to country of origin</li> <li>Assure country of origin is qualified as safe with respect to source-relevant animal diseases, including TSE</li> <li>Adventitious agent testing for animal source-relevant viruses</li> </ul>

#### PERFORMANCE TESTING

In cases where AMs are chosen for their ability to provide a particular biological function in producing the therapeutic product, performance testing becomes an essential component of their overall qualification. This is especially true when the AM plays a critical role in modulating a complex biochemical effect and has a large impact on product manufacturing yield, purity, or final product potency. These AMs tend to be complex substances or mixtures, are frequently biologically sourced, and can exhibit significant lot-to-lot variability. As a result, these AMs usually have no simple identity test, nor can they be easily characterized by physical or chemical tests. The development of well-defined performance assays for complex

AMs will not only ensure process reproducibility and final product quality, but in many cases will satisfy the identity testing criteria in accordance with 21 CFR 211.84(d).

In some cases, the initial qualification of an AM for use in manufacturing should be the investigation of the effect of the amount of the AM on the desired response (increased yield,

purity, or potency of the therapeutic product). The amount of the AM used in manufacturing should be chosen to consistently yield the desired effect while minimizing issues by removing the AM in subsequent processing steps. Such testing frequently assesses the important functional attribute expected of the AM in a scaled-down or simulated manufacturing process. Some examples follow:

- If an AM is added to the culture media because it promotes cellular proliferation or the secretion of a critical therapeutic agent, the assay could demonstrate that each lot of AMs produces the expected rate and amount of cellular proliferation or the expected level of secreted therapeutic agent.
- If a monoclonal antibody is used to purify a particular cell type, the new lot of monoclonal antibody could be shown to purify the cell population with the expected recovery and purity for the desired cell type.
  - If a deoxyribonuclease is used to degrade cellular DNA, new lots could be tested for the ability of the deoxyribonuclease to degrade DNA.
- If a particular type of density gradient material is used to purify a vector or cell, new lots of the material used to make the gradient could be shown to purify the vector or cell to an acceptable level.
- If a plasmid or viral vector is used in the production of a gene therapy vector (e.g., helper function), new lots of the helper vector could be shown to produce the expected amounts of the gene therapy vector.
- If a cell therapy is produced in a hollow-fiber bioreactor, new lots of the bioreactor could be shown to produce the anticipated amount of cell product.

The actual assay used may well evolve as the manufacturing process is developed further and the critical relationships of the AM and the final product are better understood.

Because most performance testing yields relative results, it is often helpful to assay a new lot of AMs side by side with an approved lot of AMs or an official reference standard, if available. This simultaneous comparison helps to reduce the variability due to different lots of cells or vectors and will help discern variability associated with the different lots of AMs. If performance testing involves assays to demonstrate that the new lot of AMs does not affect the impurity profile of the final therapeutic product, either by generating new impurities or by increasing the level of existing impurities, it is helpful to assay both for the total level of impurities, as well as look for the presence of new impurities. An immunologically-based binding assay can typically assess only the total level of impurities. For example, a Western blot of the gene therapy product that is probed both with antibodies to the product and antibodies to host cell proteins is useful for detecting new protein species and significant increases in the levels of host cell impurities. This initial qualification is enhanced by a performance assay that has a quantitative readout with a clear change in the signal when a significant change in the amount of AMs is introduced into the assay (e.g., dose response). A threshold-type response (i.e., there are two levels of response to the AM and neither large changes in an AM below a certain dose nor above a certain dose change the response) can make it more difficult to select a concentration of AM that consistently results in the desired effect and minimizes the residual levels of the AM in the final therapeutic product.

#### ANCILLARY MATERIALS RESIDUAL LEVEL ASSESSMENT AND REMOVAL

AMs are not intended to be present in the final dosage form in cell, gene, and tissue-engineered products. Their presence in the final product could lead to undesired effects in the recipient or have a detrimental effect on product potency. Undesired effects in humans include direct toxicity of the AM or an unwanted immunogenic response. Some examples include the following:

- In the generation of a tumor vaccine using a patient's tumor biopsy as the starting material, a chemical entity is introduced to denature the cell surface proteins and tumor antigens to enhance their antigenicity. The chemical entity is known to be highly toxic.
- Antibiotics may be added to a transport solution for human cells to address microbial contamination issues associated with the procurement procedure. Residual levels of the antibiotic may affect the proliferative capacity of the final engineered cellular product. Residual antibiotics could also cause an anaphylactic response in some individuals.
  - FBS, employed in the cultivation of an engineered human skin graft, may cause the development of a humoral antibody response directed against bovine proteins.
- Aggregated mouse immunoglobulin, a trace impurity in a purified preparation of mouse monoclonal antibody used to target a cell population for immunoselection, may be immunogenic.
  - A cytokine, employed as an immunomodulator in the generation of a gene-modified autologous tumor vaccine product, may elicit a severe reaction in the recipient.
  - Cholera toxin, employed as part of a cell culture medium for a cell therapy product intended for intravenous administration, will be highly toxic to the recipient if it is not removed during processing.

These risks can be mitigated through the design of processes to include steps to adequately remove the AM through dilution, separation, or inactivation, as well as the development of analytical detection assays to assess the AM levels during processing and in the final therapeutic product. Assessment and removal strategies for residual AMs should be considered in the early phases of process development. There are two different approaches for assessing residual AM levels in the final therapeutic product: (1) Validation studies can demonstrate that the process is capable of removing more of the AM than would be present in a worst-case scenario. (2) The residual levels of an AM can be measured for each lot at an appropriate step in the manufacturing process.

Validation of an AM removal is often best performed by spiking the impure product with "worst case" or higher levels of the AM and showing the purification process is capable of removing the AM to "undetectable levels". Clearance factors can then be generated for each purification step in a manner analogous to that done in viral clearance studies. When designing the validation studies, the following three considerations should be included: (1) The assay should be able to accurately quantitate the AM in each sample matrix. (2) If the validation is conducted at a scale smaller than that used for routine lot production, the comparability of this smaller scale process to the full scale process needs to be demonstrated. This usually means that the smaller scale process is operated using the same critical parameters as the full scale process with the product generated at each step having a similar purity and yield. (3) As with any spiking study, one has to demonstrate that the additional, higher level of AM has not affected the purification process. If the second approach of measuring residual levels of the AM in each lot is used, the specification for the maximum amount of AM in the final therapeutic product is based on the amount of the AM in the lots used in toxicological or clinical studies or known toxicological data.

The development of sensitive and reproducible analytical assays for AMs is another important component of a risk reduction approach. Two types of assays are useful in assessing the levels of residual AM impurity: a limit test and a quantitative test. Either test should be accurate, precise, robust, and have a low limit of detection. Assays for residual AMs may be performed on the product before it is formulated (e.g., on the drug substance) to avoid any interference of the components used in the formulation with the assay for residual AMs or in the final drug product. Spike-recovery controls are often included in such assays to demonstrate that the sample matrix does not inhibit the detection of the AM. Preferably, assays should be designed to detect all forms of AMs including aggregates, fragments, or conjugates. Aggregated protein has been shown to be particularly immunogenic.

Immunoassays such as ELISA are most commonly used to assess residual levels of AMs. An ELISA for bovine serum albumin (BSA) has been used to assess residual levels of FBS. Polymerase chain reaction (PCR) technology has been employed to assess residual levels of host cell DNA. Labeling cells with 3H thymidine or performing PCR for a feeder cell-specific gene sequence are two ways to assess for residual levels of feeder cells. If "wash out" of the AM is achieved by exhaustive dilution associated with further processing activities, it may be useful to calculate the dilution factor for the AM during this processing. In some cases, this is sufficient to ensure that the AM has been reduced to safe levels for early clinical development. Data should be obtained later in clinical development to confirm the wash out of the AM at the expected step(s). This approach is particularly useful when there is pre-existing knowledge of the therapeutic levels and toxicity of the AM. In other cases, information regarding the safety and tolerability of the AM should be collected (in preclinical toxicology studies or later with human clinical studies) in order to determine the safe or nontoxic levels that must be achieved. These data may be needed even for an AM that is approved for use for therapeutic purposes if it is being used in a manner inconsistent with its intended use or labeling or if the route of administration or dosage level of the AM may present risks not previously encountered or considered.

#### CONCLUSION

While many types of AMs are used during the manufacture of cell, gene, and tissue-engineered products, they have received less emphasis than the final products. However, the importance of AM quality to the quality of the final product cannot be overstated. Good quality AMs should perform as intended in a consistent manner, batch-to-batch, if they are carefully selected and appropriately used. AMs of insufficient quality will affect the quality and the effectiveness of the final product and endanger the health of patients. Thus, implementing an AM qualification program that addresses the risks associated with the AM, the stage of manufacture at which it is used, and the amount of the AM used during manufacture will ensure the safety and effectiveness of the final product.

AMs used in cell, gene, and tissue-engineered products will be regulated in the context of the manufacturing process of the cell, gene, and tissue-engineered products. Certain AMs may already be approved for uses other than for cell, gene, and tissue-engineered product manufacture. It is preferable to source AMs that are approved therapeutic products when they are available because they are well-characterized with an established toxicological profile and are manufactured according to controlled and documented procedures. The following list of documents should provide relevant regulatory guidance and a description of best practices in product and process development, manufacturing, quality control, and quality assurance:

#### 1045 BIOTECHNOLOGY-DERIVED ARTICLES

Macromolecular substances can be obtained by a number of methods including extraction from natural sources, modification of naturally occurring protein, mammalian cell culture in vitro, mammalian cell culture in vivo, production by microorganisms, and chemical syntheses. From a compendial perspective, macromolecular articles derived from biotechnology processes—or more specifically from recombinant-DNA (rDNA) technology, hybridoma technology, and transformed continuous cell lines—are those articles for which official names have been established. These articles have official public standards for identity, strength (potency), quality, and purity. Advances in genetics and the applications of genetic engineering have made the production of new and existing macromolecular articles technologically and economically feasible.

The technologies involved in producing a protein by biotechnological processes have been widely documented and general guidelines have been established by the federal government. The products of biotechnology may be regulated as drugs, biologics, or diagnostics, depending on their source, composition, and intended use. The novel approaches permitted by biotechnology can make it difficult to apply classic definitions of these categories and FDA has advised manufacturers to seek clarification in the early stages of development for how a product will be regulated when classification is not obvious.<sup>1</sup> The overall regulatory scheme for biotechnology-derived products is the same as for products in the same category produced by traditional manufacturing methods, with the addition of specific requirements suited to the biotechnology-derived product. The general requirements are described primarily in the applicable parts of the Code of Federal Regulations, Title 21. NIH has published a guideline for rDNA research that is mandatory for both public and private NIH-supported research. This guideline has wide acceptance and voluntary compliance is common by institutions and corporations not specifically governed by it.<sup>2</sup> Laboratory safety practices, particularly protection from potentially infectious materials, are a concern.<sup>3</sup> Producing macromolecular articles by biotechnological processes involves initially the cloning of a specific gene in the laboratory, or the construction of a synthetic gene, with subsequent insertion into a host cell and subcloning in a microorganism or cell culture; then a process development on a pilot scale to optimize yield and quality; and finally large-scale fermentation or cell culture processes. The next step, which is the most relevant to the development of compendial monographs, is the purification of the macromolecular proteins. This is followed by animal testing, clinical testing, regulatory approval, and marketing.

Development of relevant public standards for these macromolecular articles is generally closely linked to the processing technology used and the physicochemical and biological characteristics of a specific drug. Characterizations of these articles to ensure safety, purity, and activity should incorporate classical techniques as well as methods specific to the technology. There is always the possibility that these articles may cause some untoward effects in patients using them due to immunological sensitization as a result of a single (or multiple) molecular modification. Such a possibility requires precise characterization of these substances. Although it is theoretically possible to develop public standards for a macromolecular article, it is not possible to develop specific standards that incorporate all prospective methods of production. The compendial perspective is to develop public standards that can be applied to a final product without comprehensive knowledge of production details but which can ensure maintenance of safety, identity, strength, quality, and purity.

Testing for identity, purity, and activity generally requires the use of USP Reference Standards. It will be necessary to consider what USP Reference Standards might be required and how relevant they might be to the method of production as it relates to a final product's characteristics. Such decisions will be made on a product-by-product basis. Favorable consideration will be given to the use of USP Reference Standards that are representative of the specific products that have undergone clinical testing and are fully characterized.

Although early adoption in USP of general methods of analysis of macromolecular drugs could be conducive to early standardization of methods, the technology and analytical procedures are evolving very rapidly. Analytical procedures—chemical, physical, microbiological, and immunological—will be included in the specific product monographs.

## SCOPE OF BIOTECHNOLOGY IN THE DEVELOPMENT OF PHARMACOPEIAL ARTICLES

## Definition of Biotechnology—Historical Perspective

In its broadest definition, biotechnology refers to the use of living organisms, including isolated mammalian cells, in the production of products having beneficial use. This definition would place alcohol, antibiotic production, and dairy processing, for example, within the scope of biotechnology. However, the current interest in biotechnology is primarily a result of two major advances. The first advance was the development of rDNA technology, which allowed the genes of one species to be transplanted into another species. Thus, gene coding for the expression of a desired protein (usually human) could be inserted into a host prokaryotic or eukaryotic cell in such a manner that the host cell would then express usable quantities of the desired protein. The second major advance was the development of techniques for producing large quantities of monoclonal antibodies (i.e., antibodies arising from a single lymphocyte).

Biotechnology within the pharmaceutical industry generally refers either to the production of protein products using rDNA techniques or to the production of monoclonal antibodies. Other technologies, such as transgenic animals and plants, gene therapy, and antisense DNA, may have potential implications for the pharmaceutical industry in the future but are not within the scope of this chapter.

## rDNA Technology

The major steps in the application of rDNA technology for production of a desired protein are outlined in this section. The critical first step is identification of the protein that is to be produced, followed by the isolation of the gene of interest (i.e., the DNA sequence coding for the desired protein). Once this gene is isolated and fully characterized, it is inserted into a suitable vector such as a plasmid, which is an extrachromosomal segment of DNA usually found in certain bacteria. The plasmid is then inserted into the host cell. Clones of the transformed host cell line are isolated, and those that produce the protein of interest in the desired quantities are preserved under suitable conditions as a cell bank. As manufacturing needs arise, the cloned cells can be scaled up in a fermentation or cell culture process to produce the protein product.

Although the rDNA process is more fully described elsewhere in this chapter, the following important points should be recognized. The vector (plasmid) generally contains a selectable marker that can be used to identify cells that contain this gene. This is in addition to the gene coding for the protein of interest and the regulatory nucleotide sequences necessary for plasmid replication and messenger RNA (mRNA) transcription (the first step in protein synthesis). Selection of the desired cells is simplified because only properly transformed cells containing the selectable marker gene will survive under the growth conditions used to identify and propagate the transformed cells. Typically, the bacterial and eukaryotic selectable markers may include both antibiotic resistance or genes that complement an auxotrophic host mutation. There are numerous examples of both types of markers in each system.

Significant differences exist in the rDNA production process between prokaryotic and eukaryotic cells. In general, bacterial cells express greater concentrations of protein product and require relatively simple media components. However, prokaryotic cells do not perform many important post-translational modifications such as glycosylation and, historically, it was not possible to express large proteins in *E. coli*. These limitations necessitate the use of eukaryotic cells in many cases. The production differences between eukaryotic and prokaryotic host cells have significant impacts that are reflected in the requirements for process validation, purification, and analytical methodology. These requirements are addressed later in this chapter.

## Monoclonal Antibodies

Antibodies are proteins produced by differentiated B lymphocytes. Each lymphocyte produces an antibody of defined specificity (i.e., the antibody molecule recognizes a specific site or epitope on the antigen). Antibodies that are produced in immunized animals are formed from many different clones of B lymphocytes; hence, the name polyclonal antibodies. Because the harvest of blood from these animals, by definition, results in polyclonal antibody mixtures, the antisera have multiple epitope recognition sites with a wide variety of binding constants (avidity) and therefore vary from lot to lot. Antibodies that are produced by immortalized cell lines (hybridomas) derived from single B cells are referred to as monoclonal antibodies. The harvest of these cultures leads to an antibody of specific epitope recognition with a homogeneous binding constant.

B lymphocytes have a finite life span in culture and have to be immortalized to enable continuous monoclonal antibody production. At present, the most common procedure is through chemically-induced fusion of a mouse spleen cell with a mouse myeloma cell. The resultant mouse-mouse hybridoma cell inherits from the myeloma cell the ability to replicate continuously in culture and inherits from the spleen cell the ability to produce the desired monoclonal antibody. Cell banks of the hybridoma cell line can be used to produce a continuous supply of the monoclonal antibody, either *in vivo* (i.e., by injection into mice and subsequent collection of the ascites fluid), or *in vitro* (i.e., by conventional cell culture techniques). It should be mentioned that recent advances in molecular genetics have led to the development of transfecomas and *E. coli*- and bacteriophage-based production schemes that may offer advantages for future production of monoclonal antibodies.

Process validation, purification, and analytical considerations for monoclonal antibodies are conceptually similar to those for rDNA products. This is because both types of products are proteins and therefore require similar handling and assay procedures. Because monoclonal antibodies are the products of immortalized cell lines, there is concern that potential viral nucleic acid contaminants be effectively excluded or inactivated by the manufacturing processes, just as for recombinant products of continuous cell lines.

Commercial applications of monoclonal antibodies include both diagnostic and therapeutic uses. In some cases, the monoclonal antibody is coupled to another substance (e.g., an oncolytic agent, radionuclide, toxin), with the resultant antibody conjugate being the final product of interest. In this case, both the antibody intermediate and the final product require extensive process development and analytical characterization.

For the purposes of this chapter, the scope of biotechnology will be confined to rDNA and monoclonal antibody pharmaceutical products.

## CHARACTERISTIC PRODUCTION PROCESSES

The major difference between biotechnology-derived products and other pharmaceutical products is the means of production used to generate the product. Biotechnology makes use of genetically modified living organisms to produce protein or peptidyl products. This statement is true for both rDNA-derived products as well as monoclonal antibody products. Biotechnology-derived products are therefore readily differentiated from proteins or peptides that have been obtained by isolation from natural source materials such as plasma, serum, or tissue, or by chemical synthesis.

Biotechnology-derived products are not significantly different from other protein pharmaceuticals after the protein purification process. Thus, the basic requirements for process validation, environmental control, aseptic manufacturing, and quality control/quality assurance systems are fundamentally the same for all pharmaceutical products. However, the complexity of these systems is often greater for biotechnology-derived products because the production of such bio-molecules generally requires highly developed cell propagation processes, complicated purification methods, and analytical control to ensure their homogeneity, lot-to-lot consistency, and safety.

This section describes in some detail only those significant factors that are unique to the processing of biotechnology-derived products. This includes descriptions of the various biological production systems now in use, and a discussion of purification issues.

## rDNA Production

rDNA products are presently produced in prokaryotic (bacteria) or eukaryotic systems (e.g., yeast, mammalian cell culture). The choice of the production organism is generally a direct function of the molecular complexity of the protein that is to be produced as well as the economics and efficiency of the fermentation or cell culture process. The earliest biotechnology-derived products were produced in *E. coli* based on the high degree of understanding of its molecular biology. Within the last few years, however, the use of large-scale eukaryotic cell culture has become relatively commonplace.

## prokaryotic (bacterial) production

Bacterial production of biotechnology-derived products offers a number of distinct advantages as well as certain disadvantages. As previously stated, the biology of bacteria is quite well understood and the safe and effective use of *E. coli* as the host organism for production has been well documented. Thus, the expression of a new protein in *E. coli*, if possible, is often easier to accomplish than in other, more theoretically suitable, expression systems. This may be offset, however, by the fact that *E. coli* produces proteins usually in a chemically reduced state. For proper folding, such proteins require the production of intramolecular disulfide bonds by oxidation. A second disadvantage is that all *E. coli* proteins begin their sequence with an N-formyl methionine residue that may not always be removed by *E. coli* proteolytic systems, thus possibly yielding a methionyl derivative of the desired natural protein. A third disadvantage of expression in *E. coli* is the potential for product degradation because of trace protease impurities. A fourth disadvantage is the requirement for endotoxin removal during purification. These limitations aside, the ease of use of *E. coli* and their generally high-expression yields for most proteins often have resulted in the continued

#### preferential use of these bacteria, where feasible.

As previously described, the key element in rDNA technology is the recombinant plasmid, which contains the gene that codes for the protein of interest. Plasmids are simple and small circular extrachromosomal segments of bacterial DNA that are isolated from a bacterium and are self-replicating. The basic technology involves the specific enzymatic cleavage of a plasmid using endonucleases followed by the insertion of a new piece of DNA that contains the gene of interest. The resultant recombinant plasmid is considered the key raw material of rDNA technology. The recombinant plasmid is introduced into the host organism through a process called transformation, where it passes on its new genetic information and results in the production of the protein product. The large-scale growth of recombinant organisms can be conducted in commercial fermenters at scales in excess of 100,000 L, making these types of production systems extremely economical. There are, however, a number of issues that complicate *E. coli* fermentation systems. In some cases, the expressed protein product may cause cellular toxicity, and/or be extremely difficult to recover or purify because it may be sequestered into bacterial inclusion bodies as large semisoluble aggregates. Recent advances in *E. coli* molecular biology have led to the ability to express proteins into the periplasmic space, allowing for the removal of unwanted N-terminal methionine groups and leading to more readily purified proteins.

#### eukaryotic (mammalian cell and yeast) production

The development of eukaryotic cell culture for the production of vaccines has long been established in the pharmaceutical industry and an extensive database has been developed to ensure the suitability of such protein products in humans. The extension of this technology to rDNA products was primarily a response to the limitations in the use of *E. coli*. Particularly with respect to large proteins or glycoproteins, eukaryotic cell expression is an attractive alternative to a bacterial system because eukaryotic cells can secrete proteins that are properly folded and identical in primary, secondary, and tertiary structure to the natural human protein. Concerns about the economics of this production system originally hindered its development. Recent advances, however, in improved expression levels, in large-scale cell culture using Chinese Hamster Ovary (CHO) cells, and in the formulation of more highly defined growth media have combined to dramatically improve the economic feasibility of eukaryotic cell substrates. The number of cell passages required for cloning, selection, amplification, and cell banking prior to production generally necessitates the use of immortal cell lines because nonimmortalized strains (i.e., diploid cultures) cannot be propagated long enough to provide an economically useful time in the production stage. Initial questions regarding the safety of such immortal cell lines were based on concerns over potential oncogenes and potential viral and retroviral contamination. These concerns have been minimized by the exhaustive analysis and characterization of master cell banks for adventitious (accidentally introduced) agents, by effective process validation studies, and by the safety data gathered to date for products produced by this method. The resultant thoroughly characterized master cell bank is used for full-scale production. Other eukaryotic cell lines, such as those derived from insect cells, may be useful in achieving many of the conformational and post-translational advantages that have been described for mammalian cell culture.

The use of yeast strains such as *Saccharomyces cerevisiae* for production has been extensively explored. The production of proteins in yeast offers many theoretical advantages over *E. coli* while raising certain new concerns. Like *E. coli*, yeast can maintain stable plasmids extrachromosomally; however, unlike *E. coli*, yeast possesses the ability to produce glycoproteins.

#### monoclonal antibody production

Monoclonal antibodies can be produced in two major ways, depending on whether they are of human or murine (mouse) origin. For antibodies of murine origin, appropriate lymphocytes are selected from the spleens of previously inoculated mice or rats. The cell is then fused with a transformed cell line such as a myeloma cell line, producing a hybridoma cell. The hybridoma cells are then clonally selected and used to produce the monoclonal antibody products. For antibodies of human origin, human B lymphocytes can be clonally selected for the hapten binding specificity of their product antibodies; these selected cells can then be immortalized by infection with a virus. The resultant fused or transformed cell can proliferate indefinitely in a bioreactor/cell culture environment or can be injected into mice from whose ascites fluid the protein can be obtained. Antibody is produced as directed by the chromosomal information that resides in the cell or was acquired during fusion and is secreted into the medium from which it can be readily purified. The hybridoma cells must be thoroughly analyzed and characterized in the same general way as an rDNA cell bank. The resultant cell bank is used for production of product either by large-scale cell culture or by harvesting ascites fluid from mice inoculated with transformed cells.

#### Control of Fermentation and Cell Culture Processes

Because the production process using a living system is the fundamental cornerstone of biotechnology, the issues that relate directly to the control of biotechnology processes need to be examined. Concerns over the production of proteins in bacteria, for example, primarily involve systems for ensuring genetic stability, consistent product yield, and evidence of the lack of contamination by adventitious organisms. These same concerns apply to large-scale eukaryotic cell culture, where, as stated above, there are also significant issues relating to the use of immortalized cell lines such as the putative presence of oncogenic DNA/RNA and impurities from media proteins.

#### fermentations (bacteria and yeast)

A considerable amount of knowledge has been obtained for the production of recombinant proteins in bacteria and yeast; therefore, the major fermentation issues typically are resolved by the demonstration of consistency in fermentation conditions. Fermentations with bacteria and yeast usually are performed over short, well-defined time periods to monitor and control growth rate and product expression conditions. The presence of contaminating foreign organisms may be detected by effects on growth rate, culture purity, fatty acid profile, etc., and is cause for termination of the fermentation. The genetic stability of the production plasmid for bacteria may be addressed by isolation and nucleotide sequence analysis or by DNA restriction mapping. These results may be confirmed by peptide mapping of the expressed protein for each product lot manufactured. It is very important to optimize the fermentation conditions so that the amount of proteolytic processing of the target protein that may occur can be either limited or avoided completely. Proteolytic processing is often a problem in *E. coli* fermentations and may lead to recovery difficulties and low product yields. Finally, the conformation of the protein and its effects on potency must be addressed by the fermentation process.

#### eukaryotic cell cultures

The origin of large-scale cell culture techniques for the production of biotechnology-derived products can be traced back to the vaccine industry. Developments such as large-scale cell suspension cultures using recombinant organisms that secrete the desired protein into the media have had a significant impact on biotechnology. Large glycosylated proteins in quantities sufficient for the marketplace can now be produced. The use of eukaryotic cell cultures, however, is complicated by issues such as genetic stability, protein folding, and culture conditions, including cell viability and growth rates. For example, the genetic stability of cell cultures cannot be addressed as readily as *E. coli* fermentations by techniques such as plasmid sequence analysis because the gene that codes for the product is incorporated into the cell genome and is not easily recovered. One alternative is peptide mapping of the expressed protein, which requires a resolution and sensitivity adequate to detect subtle mutations.

The absence of adventitious organisms in cell cultures is critical. In addition to demonstrating that bacteria, yeast, and molds are not present in cell cultures, the manufacturer must provide for each culture evidence that mycoplasmas and adventitious viruses are not present. It is important to recognize that certain hybridomas used for monoclonal antibody production may contain endogenous retroviruses. However, it must be demonstrated that any viruses present in the culture are removed from the final product. This requires the development of suitable analytical techniques to ensure the absence of contamination by mycoplasmas or human and animal adventitious viruses.

The degree and type of glycosylation may be important in the design of cell culture conditions for the production of glycosylated proteins. The degree of glycosylation present may affect the half-life of the product *in vivo* as well as its potency and antigenicity. Although the glycosylation status of a cell culture product is difficult to determine, it can be verified to be consistent if the culture conditions are highly reproducible.

#### Process for Recovery and Purification

The recovery of protein products obtained from either fermentation or cell culture is generally based on efficient protein separation techniques such as those listed in [Table 1](#). The recovery process begins with isolation of the desired protein from the fermentation or cell culture medium, often in a very impure form. The advantage of cell culture and yeast derived products is that many of these proteins are secreted directly into the medium, thus requiring only cell separation to obtain a significant purification. For *E. coli*-derived products, lysis of the bacteria is often necessary to recover the desired protein. It is important in each case to achieve rapid purification of the desired protein because proteases released by the lysed organisms may cleave the desired product. Such trace proteases are a major concern in the purification of biotechnology-derived products because they can be very difficult to remove, may complicate the recovery process, and can significantly affect final product stability.

Table 1. Chromatographic Purification Methods Used for Biotechnology-derived Products

Chromatofocusing
Reversed-phase chromatography
Hydrophobic interaction chromatography
Charge-transfer chromatography
Size-exclusion chromatography (molecular sizing)
Ion-exchange chromatography
Anion
Cation
Affinity chromatography
Chemical
Monoclonal antibodies
Cellular receptors
Dye/Ligand
Metal chelate

The recovery process is usually designed to purify the final product to a high level. The purity requirement for a product depends on many factors, although chronic use products may be required to have much higher purity than those intended for single-use purposes. Biotechnology products contain certain impurities that the recovery processes are specifically designed to eliminate or minimize. These impurities include trace amounts of DNA, growth factors, residual host proteins, endotoxins, and residual cellular proteins from the media. The most common impurities of concern and suitable assay methods to detect them are presented in [Table 2](#).

Table 2. Potential Impurities and Contaminants in Biotechnology-derived Products

Impurities or Contaminants	Detection Method
Impurities	
Endotoxin	<a href="#">Bacterial Endotoxins Test</a> (85), <a href="#">Pyrogen Test</a> (151)
Host cell proteins	SDS-PAGE <sup>a</sup> , Immunoassays

Chromatofocusing and reversed-phase chromatography are purification methods that use chemicals, either in the stationary (bonded) phase or in the mobile phase, that may become impurities in the final product. As in any new technology, the burden of validation (i.e., demonstrating removal of potentially harmful chemicals) is incumbent on the manufacturer. Validation is necessary when isolating end product monoclonal antibodies or using a technique that contains a monoclonal antibody purification step. The process must demonstrate removal of leaching antibody or antibody fragments. It is necessary to ensure the absence of adventitious agents such as viruses and mycoplasmas in the cell line that is the source of the monoclonal antibodies. The main concern is the possibility of contamination of the product with an antigenic substance whose administration could be detrimental to patients. Continuous monitoring of the process is necessary to avoid or limit such contamination. The problem of antigenicity related to the active as well as host proteins is one that is unique to biotechnology-derived products in contrast to traditional pharmaceuticals. Manufacturing methods that use certain solvents should be monitored if these solvents are able to cause chemical rearrangements that could alter the antigenic profile of the drug substance. The manufacturer is also obligated to produce evidence regarding performance consistency of novel chromatographic columns. Considerations for single-use products such as vaccines may differ because they are not administered continuously and, in this case, antigenicity is desirable. On the other hand, validating the removal of ligand or extraneous protein contamination is necessary. Unlike drugs derived from natural sources, manufacturers of biotechnology-derived products have been required to provide validation of the removal of nucleic acids during purification. Vaccines may again be different in this regard because of the accumulated clinical history on these products.

#### QUALITY CONTROL

In general, quality control systems for biotechnology-derived products are very similar to those quality control systems routinely employed for traditional pharmaceutical products in such areas as raw material testing and release, manufacturing and process control documentation, and aseptic processing. Quality control systems of biotechnology-derived products incorporate some of the same philosophies applied to the analysis of low molecular weight pharmaceutical products. These include the use of chemical reference standards and

...ated methods to evaluate a broad spectrum of known and/or potential product impurities and potential breakdown products. The quality control systems for biotechnology-derived products are generally analogous to those established for traditional biologicals with respect to determining product sterility, product safety in experimental animals, and product potency. For example, refer to [Injections](#) (1), [pH](#) (791), [Particulate Matter in Injections](#) (788), [Bacterial Endotoxins Test](#) (85), and [Impurities in Official Articles](#) (1086).

The fundamental difference between quality control systems for biotechnology-derived products and traditional pharmaceuticals is in the types of methods that are used to determine product identity, consistency, purity, and impurity profiling. Furthermore, in biotechnology quality control, it is frequently necessary to use a combination of final product and validated in-process testing and process validation to ensure the removal of undesired real or potential impurities to the levels suggested by regulatory agencies. Biotechnology-derived products generally require a detailed characterization of the production organism (cell), a complete assessment of the means of cell growth/propagation, and explicit analysis of the final product recovery process.

The complexity of the quality control systems for biotechnology-derived products is related to both the size and structural characteristics of the product and manufacturing process. In general, the quality control systems required for products produced in prokaryotic cells are less complex than the systems required for products produced in eukaryotic cells. The quality control systems for prokaryotic production organisms usually entail documentation of the origin of the producer strain and encompass traditional testing for adventitious organisms, karyology, phenotyping, and antibiotic resistance. In addition, newer techniques such as DNA restriction mapping, DNA sequence analysis, and routine monitoring that may include measurement of mRNA and/or plasmid DNA levels may be useful. The quality control of the master cell bank and working cell bank for eukaryotic production organisms generally includes testing for adventitious organisms, karyology, identity, and stability monitoring. All eukaryotic cell lines (except yeast) are generally tested for the presence of retroviruses, retroviral activity markers, and tumorigenicity, although many of these tests may be of limited value.

#### PRODUCT FORMULATION

The products of biotechnology are proteins and peptides that are relatively unstable molecules compared to most organic pharmaceuticals. Most biotechnology processes involve the transfer of proteins from one stabilizing or solubilizing buffer to another during the purification process. Ultimately, the protein is exchanged into its final solution dosage form where long-term stability is achieved. In addition, these products often require lyophilization to achieve long-term stability because of the potential for degradation by a variety of mechanisms, including deamidation, aggregation, oxidation, and possible proteolysis by trace levels of host cell proteases. The final dosage form of the protein usually contains stabilizing compounds that result in the optimal pH and solution conditions necessary for long-term product stability and/or the desired properties for administration of the product (tonicity). These compounds include proteins, polyhydric alcohols, amino acids, carbohydrates, bulking agents, inorganic salts, and nonionic surfactants. In addition, these excipients may be required for stable lyophilized cake formation. There are special requirements for lyophilized products, such as the control of moisture levels, that generally are defined in the individual USP monograph and that may be important to product stability. Significantly, the assessment of protein stability usually requires the use of multiple analytical methods, each of which may be used to assess a specific mode of protein degradation. Many of these assays are described in the following section. The use of accelerated stability studies to predict the shelf life of protein formulations is often complicated by the effects of temperature on protein conformation, resulting in non-Arrhenius behavior. Thus, reliance on real-time, recommended storage condition stability studies is often required for establishing the expiration dating of biotechnology-derived products.

#### ANALYTICAL METHODOLOGY

The analysis of biotechnology-derived products relies heavily on the use of sophisticated analytical methods for demonstrating the structural identity and homogeneity of proteins and for evaluating the shelf life or stability of these products. This section discusses accuracy, precision, informational content, and general applicability of the most commonly used methods. Some methods, such as host cell impurity assays and residual DNA procedures, may be both highly process- and product-specific and thus should be included in the individual monographs.

##### Reference Standard Considerations

The use of suitable reference standards and/or reference materials is extremely important in the analysis of biotechnology-derived products. These standards may be either natural materials or proteins produced by genetic engineering. Many biotechnology-derived products require the availability of accurately characterized reference standards from internationally recognized sources such as the USP (see [USP Reference Standards](#) (11)), WHO, NIH, and FDA. Currently, reference standards with defined activity units are available from these sources for some biologicals. These standards are used by the manufacturers in testing or to calibrate secondary standards using many of the assays described in this section. The potency value of the reference standard is obtained through collaborative studies that, when statistically evaluated, are used to determine the ultimate potency value assigned to the reference standard. The secondary standard can be used to determine the labeled amount of drug substance or potency defined on a product label. Thus, reference standards/reference materials for biotechnology-derived products that are used for the analytical purposes described in specific USP monographs will be approved and made available from USP. Ideally, these reference standards should be in use worldwide and should always be calibrated against the U.S. standard that is deposited by the manufacturer at FDA for those products licensed by FDA. This ensures the accurate and consistent determination of the activity, strength, and purity of these products. Because of a number of issues unique to biotechnology-derived products, such as process and product specificity, separate reference standards for similar products may be required. In addition, thorough development and recalibration of reference standards to replace depleted or expired standards will be conducted by USP to ensure that the label claims of the drug products do not change. One caveat in the assignment of the potency of the primary standard through collaborative studies is that units of activity so defined are only meaningful when compared in a single assay that is both suitably accurate and well described. Attempts to compare activity values from even subtly different assays can be expected to yield widely varying results.

##### Typical Methodology

There are a number of specific analytical methods that pertain to biotechnology-derived products. Many of the assays and tests described may be performed in different ways and, because some of these may be product specific as well, there is a need for clear guidelines on the application of specific methods to particular situations. See the chapters [Design and Analysis of Biological Assays](#) (111) and [Validation of Compendial Procedures](#) (1225) for some general information on methodology.

##### protein content

Protein content assays are used to quantitatively determine the amount of protein in a given biotechnology-derived product. The determination of protein content is often one of the most difficult measurements that needs to be made and often requires independent confirmation by alternate methods. Where applicable, methods such as UV spectrophotometry with a valid absorptivity and Kjeldahl nitrogen analysis can be used to determine absolute amounts of protein independent of reference standards. However, methods such as Lowry protein, biuret, and quantitative amino acid analysis, which require reference standards, also yield accurate values. Protein content assays are among the most important of all the methods used for these products because the results of other types of assays, such as potency, are also dependent on them.

There are several assays for the determination of protein content that are commonly used. These assays may be used at different points in the production process of a given biotechnology-derived product. For highly pure proteins, the simplest protein content method is based on the determination of the UV absorbance of a protein solution by spectrophotometry. The absorbance at the absorption maximum is determined and the protein concentration is calculated with the use of an empirically determined absorptivity. This technique is applicable to proteins containing the aromatic amino acid residues tryptophan, tyrosine, and/or phenylalanine. The absorption wavelength often used is 280 nm. The extinction coefficient, or molar absorptivity, should be determined in the same solvent that is used for the sample to be measured. If necessary, the product may be diluted prior to analysis to obtain solutions with absorbance values in the linear range of detection. Higher molecular weight aggregates and particulates may give rise to light-scattering effects, which provide artificially high absorbance values. Excipient components that have significant absorbance at 280 nm will also interfere with this test. UV spectrophotometry is unique among the protein content methods in that it is an absolute measure of concentration of a specific protein requiring no calibration with standards.

A commonly used general protein content method is the Lowry assay. This is based on the biuret reaction of proteins with copper (II) in a basic solution and the Folin-Ciocalteu phosphomolybdate-phosphotungstic acid reduction to heteropolyphosphomolybdate blue by the copper-catalyzed oxidation of the aromatic amino acids tyrosine, tryptophan, and phenylalanine in the protein. The reaction products are blue and are quantitated spectrophotometrically in the visible region between 540 and 560 nm. This reaction is linear at microgram protein levels. The assay, however, is prone to interferences from a number of substances such as alcohols, sugars, and detergents. In some cases, interfering substances or product may be removed prior to analysis, e.g., by precipitation. Also, the preparation of controls containing interfering substances that are in the drug product may correct for their presence. Although bovine serum albumin historically has been used to prepare the standard curve, different proteins are known to react with differing intensity, so that a reference material of the same product should be used for calibration. The bicinchoninic acid (BCA) assay is a useful alternative to the Lowry assay because it is less sensitive to interfering substances. The working reagent is a BCA-copper (II) solution. The copper (II) complex is reduced to copper (I) in the presence of protein, and the purple color may be quantitated

spectrophotometrically at approximately 560 nm.

Other colorimetric assays can also be used. The Bradford method, for example, employs the binding of the dye Coomassie Brilliant Blue to the protein in an acidic environment. The concentration of the protein in solution is then determined by comparing the absorbance at 595 nm with a standard curve of a reference material.

Fluorescent methods used are normally based on either fluorescamine or o-phthaldialdehyde (OPA). The main advantage of these assays is increased sensitivity. Another advantage is their use with hydrophobic proteins. Fluorescamine and OPA react with primary amines both at the N-terminus of the polypeptide and with amino acid side chains, such as lysine.

The Kjeldahl nitrogen method, [Nitrogen Determination](#) (461), provides an accurate and precise determination of protein concentration and is often used in the determination of UV protein absorptivities. The assay is performed in two stages. The sample is first decomposed with sulfuric acid to produce ammonium sulfate, carbon dioxide, and water. The decomposition is performed at the boiling point of sulfuric acid in long-necked, pear-shaped flasks. These flasks serve to condense water vapor and prevent the loss of material.

Depending on the efficiency of decomposition, various salts such as potassium sulfate may be added to increase the boiling point of the sulfuric acid solution. Oxidizing agents such as perchloric acid or potassium permanganate have also been used to improve the decomposition. The second stage of the assay involves the direct determination of ammonia. In most macrodeterminations, ammonia is steam distilled from the mixture after basification with sodium hydroxide. The ammonia can typically be quantitatively distilled out of the mixture in 5 to 20 minutes and absorbed quantitatively into a standardized acidic solution of known volume and normality. The excess acid is then back-titrated with standardized base. For crude determinations of protein, the ammonia value (and therefore the nitrogen content), is multiplied by a factor of 6.25 mg of protein per mg of nitrogen, which corresponds to a nitrogen content of 16%. The protein value so obtained is generally valid for most proteins. If a more accurate value is required, as for an absorptivity determination, then the conversion factor must be calculated for the nitrogen content of the individual pure protein from the known amino acid composition. For glycoproteins that contain amino sugars, the calculated value is biased high unless a correction is applied.

Amino acid analysis is used in the determination of the appropriate absorptivity of the protein and may also be used quantitatively for the determination of protein content. This procedure, although more complicated than those described above, can also yield accurate results.

#### amino acid analysis

Amino acid analysis is a classical protein chemistry method for the determination of the amino acid composition of proteins and peptides. The method consists of the complete hydrolysis of a protein or peptide to its component amino acids, which are then chromatographically separated and quantitated. Amino acid analysis, therefore, can be used to determine both the amino acid composition of a product (i.e., identity) and the total amount of protein present. The method has some inherent difficulties, such as complete or partial destruction of some amino acids, that can be circumvented by appropriate analytical methodology. The amino acid tryptophan is destroyed by 6 N hydrochloric acid hydrolysis and thus requires the use of alternate hydrolysis conditions. The amino acids serine and threonine may be partially destroyed, whereas peptide bonds between bulky hydrophobic residues such as valine and isoleucine may be more resistant to hydrolysis, in both cases yielding values lower than actual. Accordingly, analysis of time-course hydrolysis samples may be used to compensate for these factors. Cysteine and methionine may require preoxidation to cysteic acid and methionine sulfone, respectively, for accurate quantitation. Each specific protein may require a procedure of optimized hydrolysis conditions for its amino acid analysis to obtain the optimal results.

Amino acid analysis is performed in two stages. The first stage involves the hydrolysis of the protein into its component amino acids. This hydrolysis is normally performed with 6 N hydrochloric acid at about 110° for 24 hours. Some proteins may require longer or more stringent hydrolysis conditions. The second stage is the separation and quantitation of the individual amino acids by some form of chromatography that can be performed with either precolumn or postcolumn derivatization. A number of precolumn derivative procedures are available, such as with OPA, phenylisothiocyanate (PITC), and fluorenylmethoxycarbonyl (FMOC). These derivatives are then separated by reversed-phase (RP) high-performance liquid chromatography (HPLC) and quantitated following UV or fluorescence detection. Postcolumn derivative methods involve separation of the component amino acids by high-performance ion-exchange chromatography (HPIEC) followed by postcolumn reaction with a chromophore, such as ninhydrin, and quantitation following UV/visible detection. All of these methods are suitable for performing amino acid analyses and each has its inherent advantages and disadvantages. OPA derivatives are very simple to prepare and are sensitive, requiring only a small amount of sample, but they are unstable and have to be chromatographed immediately upon preparation. Phenylthiocarbamyl (PTC) derivatives, on the other hand, are relatively more stable. Postcolumn derivatization with ninhydrin is often performed in the low-pressure mode and has the advantage of stability of the amino acid hydrolysate. Its disadvantage is the need for dual detection at 440 and 570 nm and for post-column apparatus.

#### PROTEIN SEQUENCING

Protein sequencing is useful in the control of quality of protein biologicals because it can provide primary structure information, i.e., amino terminal and/or carboxy terminal structure. For rDNA-derived biologicals, this methodology has the additional purpose of confirming the complementary DNA (cDNA)-predicted amino acid sequence, protein homogeneity, and the potential extent of proteolytic clips. For monoclonal antibodies, this technique is used for determining protein homogeneity. Protein sequencing is divided into amino-terminal and carboxy-terminal sequencing applications and procedures.

**Amino-Terminal Sequencing**— Amino-terminal sequence analysis is a classical protein chemistry technique that yields significant information about primary structure (sequence), homogeneity, and the presence of known or unknown cleavages in the polypeptide. N-terminal sequence analysis is performed with a number of commercially available automatic peptide sequencers. The method is based on the coupling reaction of the amino terminal residue of a protein or peptide with PITC. The resulting PTC-amino acid derivative is cleaved from the protein by a perfluorinated organic acid (generally trifluoroacetic or heptafluorobutyric acid), which exposes the adjacent amino acid. This next amino acid serves as a new N-terminus and is derivatized in the subsequent coupling and cleavage cycle. This process is repeated until an appropriate number, normally 8 to 10, of the amino acids are removed. The modified amino acid residue resulting from the cleavage cycle (anilinothiazolinone [ATZ]) is generally converted in the presence of acid and heat to a phenylthiohydantoin-amino acid (PTH-AA). The PTH-AA may then be determined following RP-HPLC analysis. Any intrachain cleavages as well as heterogeneity of the N-termini (e.g., N-terminal methionine) on the polypeptide will also be sequenced at the same time. These result in smaller peaks in the chromatogram and may enable both the relative quantitation of the amount of the N-termini and the identification of the location of the cleavage site on the polypeptide. This procedure for protein sequence analysis may also be performed manually. The limitations of the PITC sequencing method are that the method is only semiquantitative (i.e., the amount of the N-termini can only be estimated) and the PTH derivatives of serine and threonine may be severely degraded, making their determination difficult. Cysteine residues in order to be determined, must first be modified, for example by alkylation. In addition, the amino acids glycine and proline are slow to rearrange, resulting in minor difficulty in their determination.

**Carboxy-Terminal Sequencing**— Sequencing of the protein from the carboxy terminus also yields valuable primary structure information as well as possible C-terminal cleavages. The sequential degradation of a protein from the C-terminus can be performed by either chemical or enzymatic methods. The reaction of hydrazine, ammonium thiocyanate, or cyanogen bromide with a protein can be used to sequentially degrade the protein at or near the C-terminus. The ammonium thiocyanate reaction has been extended for use on proteins coupled to solid supports. The C-terminal amino acids can be sequentially cleaved enzymatically with exopeptidases such as carboxypeptidases. Limitations of the carboxypeptidase approach are the potential contamination with endopeptidase and the inherent difficulty and unpredictable nature of the sequencing. Mass spectrometry can be used either directly on protein digests or in conjunction with HPLC peptide mapping to identify the C-terminus of the protein. However, these methods are only semiquantitative.

#### peptide mapping by hplc

For pharmaceutical proteins, peptide mapping has two primary purposes: it is a highly specific identity method and, in the case of biotechnology-derived products, may serve as a confirmation of genetic stability. Peptide mapping is used to compare the protein structure of a specific lot of material to that of a suitable reference material/reference standard or to those structures of previous lots to confirm correctness of the primary structure and to confirm lot-to-lot consistency of primary structure (within the limits of this technique). The amino- and carboxy-terminal peptides and carbohydrate-containing peptides often can be separated and identified. The latter are valuable in the peptide maps of glycosylated proteins such as monoclonal antibodies. Peptide mapping may be used to determine the presence of single or multiple incorrect amino acids that may result from such events as a single point mutation or mistranslation of the cDNA sequence.

The procedure involves the selective fragmentation of the protein into discrete peptides that are resolved by some chromatographic technique. The fragmentation is accomplished with endoproteases, such as trypsin, chymotrypsin, thermolysin, or V8 protease, or by selective chemical degradation with cyanogen bromide, which cleaves at specific sites on the molecule. Selection of the appropriate endoprotease to be used is directed by the primary sequence of the protein. Trypsin cleaves on the C-terminal side of the basic residues lysine and arginine; chymotrypsin cleaves after the aromatic residues phenylalanine, tyrosine, and tryptophan; thermolysin cleaves after the hydrophobic residues leucine, isoleucine, and valine; V8 protease cleaves after the acidic residues glutamic acid and aspartic acid; and cyanogen bromide cleaves at methionyl residues. Other enzymes, such as clostrin (arginine) and endoproteinase lys-C (lysine), and chemical methods, such as 2-nitro-5-thiocyanobenzoic acid (cysteine), may also be used. Each of these methods has its own set of

antages and disadvantages. One common disadvantage to all these techniques is that nonspecific cleavages occur to some degree. It is important that the peptides generated from the digestion are large enough to provide structural information about the protein, and yet small enough to allow their analysis and separation by a technique such as RP-HPLC. For this reason and the fact that cleavage with this enzyme is almost quantitative, trypsin is the enzyme with the most general applicability for most proteins. For large proteins of greater than 60,000 daltons (about 520 amino acids), cleavage with trypsin may result in too many fragments, so another endoprotease may be chosen. I-TPCK (tosyl-l-phenylalanine chloromethyl ketone)-treated trypsin normally is used because TPCK inhibits the action of chymotrypsin, a contaminant present in many trypsin preparations. Although reaction with cyanogen bromide cleaves at methionyl residues, proteins do not contain many of these residues. As a result, relatively few peptides are obtained and these may be too large or hydrophobic for HPLC separation.

Once the digestion is complete, the peptides are generally separated by either RP-HPLC and/or HPIEC. Selection of the appropriate column is empirically based and will vary for different proteins. For RP-HPLC, both 100-Å and 300-Å pore size supports work well, and the selection of the silica support may be an important criterion for optimal separation. For the smaller peptides generated by these digestions, C8 and C18 stationary phases generally have been found to be more efficient than C4 supports. The most common solvents used

for reversed-phase separations are water and acetonitrile containing a constant (~0.1%) amount of trifluoroacetic acid. Buffered mobile phases containing phosphate also offer excellent selectivity depending on the pH. Screening the effect of pH in the 3.0 to 5.0 range causes a shift of peptides containing the acidic residues, glutamic acid and aspartic acid.

For ion-exchange separations, less information is available, but both silica and polymeric supports with both weak and strong ion-exchange stationary support can be used successfully. Because many of the peptides are somewhat hydrophobic, the addition of small amounts of organic solvents in the mobile phase, such as 5% to 10% methanol or acetonitrile, may be necessary. A potential disadvantage of HPIEC analysis of peptide mixtures is that sometimes neutral peptides or peptides that have the same charge as the support may not be retained on the column and thus may not be separated or identified by this method.

#### immunoassays

Immunoassays are used either as active drug substance methods to identify and quantitate the protein of interest or as impurity profile methods to detect and quantitate known host cell protein impurities. Because these protein impurities may represent a large number of potential impurities at trace levels rather than a single impurity, the immunoassays must be sensitive and selective to detect as many of these impurities as possible. Immunoassays that can measure these impurities to very low levels have been developed for E. coli proteins (ECPs) and CHO proteins. Immunoassays additionally may serve as potency assays for monoclonal antibodies using an appropriate antigen.

Immunoassays consist of a large group of assays that depend on specific high-affinity antibody:antigen interactions. These assays include the radioimmunoassays (RIAs) and the enzyme-linked immunosorbent assays (ELISAs). RIAs are performed in a liquid or solid phase using an unlabeled antibody directed against the radiolabeled protein of interest. The principle of the RIA is that the inhibition of binding of labeled antigen to unlabeled antibody by samples is compared to the inhibition by known standards, thus allowing quantitation of the protein of interest.

Immunoradiometric assays (IRMAs) or sandwich RIAs employ two antibody preparations that are used to sandwich the protein of interest. The first antibody is unlabeled and is directed against the protein, and the second antibody is radiolabeled and may be directed against the protein or the first antibody. The entire antibody:antigen complex is isolated and the amount of radioactivity, and, therefore, the protein of interest, is determined. The development of an RIA or IRMA for a biotechnology-derived product requires careful attention to production of the antiserum, preparation of the labeled tracer, preparation of a suitable reference standard, and methods for the separation of free antigen from bound antigen.

The most commonly used ELISA format of trace impurity analysis is the sandwich ELISA that utilizes two antibody preparations like the IRMA, but without radiolabeling. The first antibody is unlabeled and the second antibody has an enzyme such as horseradish peroxidase (HRP) or alkaline phosphatase attached. Basically, the ELISA method consists of applying a layer of purified antibodies to the host cell proteins onto microtiter plates, followed by the protein product. The enzyme antibody conjugate is added and allowed to bind to the antibody-bound host cell proteins. An appropriate substrate is added for color development, which is analyzed with a spectrophotometric plate reader. Such a multiantigen ELISA requires a representative reference standard preparation of appropriate host cell protein impurities to serve as the immunogen for preparation of the antibodies used for the assay. This reference standard preparation is usually prepared from a manufacturing production run yielding all of the expected host cell proteins except the product protein. The total absence of the product protein is necessary in this preparation to avoid the production of antibodies to the product itself when the reference standard is used as an immunogen. Because of varying affinities of polyclonal antibodies to multiantigen preparations, the absolute accuracy of the multiantigen methods and the ability to detect every potential antigen cannot be guaranteed.

#### electrophoresis

Electrophoretic assays are among the most common and powerful of the assays used to evaluate protein purity and homogeneity. They are valuable not only for the initial evaluation and release of biotechnology-derived products but also as stability-indicating methods for detecting molecular or chemical changes in the molecule as a result of denaturation, aggregation, oxidation, deamidation, etc. The use of these methods is facilitated by their simplicity and their requirement of only microgram quantities of sample. The two types of electrophoretic assays most often used for biotechnology-derived products are sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and isoelectric focusing (IEF).

The SDS-PAGE method separates proteins primarily by their molecular weight because, in the presence of the anionic detergent SDS, a net negatively charged protein SDS complex is formed. The sample is first denatured in the detergent, which disrupts the noncovalent intramolecular and intermolecular bonds that hold proteins together, and then it is electrophoresed through a polyacrylamide gel support. Protein migration through the gel is proportional to size so that smaller proteins migrate faster through the gel than larger ones. Samples are often electrophoresed under both reduced and nonreduced conditions to determine if impurities of the same molecular weight or if intramolecular proteolytic cleavages of the protein of interest are present. Although nonreducing SDS-PAGE is commonly used to estimate the state of aggregation and/or oligomerization of the protein of interest, this method will only permit observation of aggregates or oligomers that are stable in the presence of SDS and the conditions used for sample preparation and electrophoresis. Proteins consisting of multiple chains held together by disulfide bonds are broken down and separated into their individual polypeptide chains. Sample detection following electrophoresis can be quantitative with densitometric analysis of Coomassie Brilliant Blue stain or qualitative, but with increased sensitivity in the nanogram range, with silver stain. Silver stain SDS-PAGE may also be performed quantitatively under suitable conditions. With proper validation, Coomassie Brilliant Blue staining and densitometry may also be used to give quantitative determination of polypeptides in the nanogram range. SDS-PAGE coupled with Coomassie Brilliant Blue stain is used to quantitatively determine the purity of the sample with regard to dimer and larger covalent aggregates and fragments. When the method is combined with the silver stain technique, an assessment of low/trace levels of a new impurity can be made by directly comparing the electrophoresed sample to the electrophoresed reference material or standard under reduced and nonreduced conditions. Generally, silver staining is used qualitatively because of potential major variations in binding of silver from protein to protein, and relatively inconsistent background on a routine basis. An estimation of the quantity of an impurity can be obtained by electrophoresis of a known amount of an internal standard such as bovine serum albumin or lesser dilutions of the protein of interest on other lanes of the same gel. The SDS-PAGE separation of a protein can be combined with an immunological method such as immunoblotting. The resulting Western blot is used to determine the identity of an electrophoretic band (i.e., product related or host cell protein impurity). After electrophoresis, the separated proteins are transferred onto a nitrocellulose or polyvinylidene difluoride (PVDF) membrane and reacted with the antibody of interest. Visualization of the complex is done with an enzymatically or radiolabeled antibody.

The IEF method separates proteins on the basis of their charge in an electrical field. The charges on a protein originate from various sources within its amino acid composition, such as protonated amino groups, unprotonated carboxyl groups, deprotonated sulfhydryl groups or tyrosine residues, oxidized cysteine residues, and deamidated residues. However, for each protein there is a pH at which the protein is isoelectric and these charges cancel each other, with the net charge being effectively zero. IEF is performed in the native state in a support of loose-pore polyacrylamide or agarose gel containing ampholytes (amphoteric low molecular weight ions) that set up a pH gradient because of their migration within the support matrix when an electrical field is applied. Simultaneously, in the presence of the electrical field, positively charged proteins migrate towards the cathode and negatively charged proteins migrate towards the anode. Migration stops when each protein reaches the pH value in the support gradient where its net charge is zero. This is the apparent pI or isoelectric point of the protein. Because the migration of a protein is dependent on its amino acid composition, altered forms of the protein and other proteins will migrate to different points on the support. IEF gels may be stained for protein visualization with either Coomassie Brilliant Blue or silver stains. IEF is employed as an identity tool or to ensure the homogeneity of a protein (e.g., monoclonal antibodies) as demonstrated by a banding pattern with the correct pI range. The method can also be used to evaluate the stability of a biological product. Protein deamidation (i.e., glutamine or asparagine residue deamidation) over time leading to the production of a new carboxylic acid group results in molecules with a more acidic pI. IEF can provide information on the state of glycosylation of glycoproteins such as monoclonal antibodies, which may appear as many bands because of changes in the apparent charge on the protein molecule as a result of the sialic acid residues. IEF gel patterns are usually more complicated to interpret than those of SDS-PAGE and interpretation may require many assumptions or subjective judgment.

High-performance capillary electrophoresis (HPCE), which offers the potential advantages of very high protein resolution, is being thoroughly investigated because of recent advances in the technology.

## chromatographic methods

Chromatographic methods have long been used in the determination of the purity of small organic molecules and proteins such as insulin (see [Chromatography](#) 621) and in the determination of the active ingredient and/or excipient concentration of pharmaceutical products. Chromatographic methods are also very effective in the determination of the purity of recombinant pharmaceuticals. However, the chromatography of proteins is far more difficult because of multiple modes of interaction with the chromatographic support as a result of the size and/or shape, charge, and hydrophobicity of the proteins. The most common chromatographic methods used to profile recombinant proteins are RP-HPLC, HPIEC, size-exclusion chromatography (HPSEC), and hydrophobic interaction chromatography (HIC). These methods involve the separation of proteins and are used to determine the purity of drug substances as well as the levels of known impurities or degradation products. A complication with all column chromatographic methods is determining the mass balance between column load and column eluate. Nevertheless, HPLC techniques are valuable for determining the purity and strength of protein pharmaceuticals.

The most common RP-HPLC analyses are performed on columns containing a C4 or C8 stationary phase on a silica-based or polymeric support. C18 stationary phases are also used but more often with smaller peptides in an application such as peptide mapping. Supports with pore sizes of at least 300 Å are preferred for proteins of molecular weight greater than about 10,000. For most RP-HPLC analyses, the proteins are eluted with aqueous acetonitrile gradients and the trifluoroacetic acid is kept constant at 0.1%. Other buffers such as phosphate or tris(hydroxymethyl)aminomethane (Tris) are also used, where the pH may be adjusted for added selectivity to achieve optimal separations.

HPIEC is an important method for purity determination. These separations are based on changes in the charge of the molecule and are useful for identifying and quantitating in protein pharmaceuticals common impurities such as oxidized (primarily oxidized methionine) and deamidated forms (glutamine and asparagine) and clipped or truncated forms. Both strong and weak ion-exchange stationary phases on either silica or polymeric supports can be used. Cation-exchange chromatography may be performed on sulfopropyl-type resins and are effective in distinguishing oxidation and deamidation products. Proteins are typically loaded onto a column equilibrated with water or a weak buffer, and eluted with a salt gradient, such as 0 to 1 M sodium chloride.

HPSEC is a technique that may provide information on the levels of aggregation and fragmentation in a protein pharmaceutical. Depending on the information needed, the mobile phase may be native, containing an aqueous buffer such as 100 mM phosphate, pH 7, or it may be denaturing, containing a low level of a chaotrope or detergent such as 0.1% SDS. The analyses are performed isocratically, with detection typically between 210 and 220 nm depending on the buffer used. Detection at 280 nm may also be used but is less sensitive. Classical size-exclusion chromatography was performed on soft polymeric supports such as cross-linked dextrans, polyacrylamide, or agarose. These, however, are better suited for low-pressure applications. As a result, a number of supports with increased mechanical strength have been developed. Commercially available silica-based and cross-linked agarose supports are now commonly used. HPSEC is also useful for the determination of clipped forms of proteins. Clipped chains often remain attached through the disulfide bonds of cysteine residues. Treatment of the sample with a reducing agent such as dithiothreitol or mercaptoethanol will cleave the disulfide bond and separate the chains. The clipped chains may then be resolved from unclipped forms by HPSEC.

HIC provides separation of proteins based on differences in their hydrophobicity under mild adsorption and elution conditions that generally prevent denaturation and subsequent loss of biological activity. A stationary phase that is weakly hydrophobic is used with a buffered aqueous mobile phase and an initial high-salt concentration to adsorb the protein, which is then selectively eluted using a decreasing salt gradient. Interactions occur between nonpolar amino acid residues that are exposed on the surface of the protein and hydrophobic groups that are present on the chromatographic matrix. A number of silica-based and polymeric supports combined with weakly hydrophobic ligands, such as polyethers, phenyl ethers, or short alkyl chains, have been developed for use in HIC. This technique can be used in the analysis, purification, and characterization of more labile hydrophobic proteins. Protein retention and selectivity can be modified by control of variables such as salt type and concentration, pH and selective-ion effects, temperature and gradient design, as well as by careful selection of the stationary phase.

## quantitative assays

Biomimetic assays (assays that mimic the biological effect of the product) are of major significance in the discussion of assays for biotechnology-derived products. These assays measure the activity of the product and ensure that it is efficacious. Essentially, there are three major types of quantitative assays: animal model assays, cell culture-based assays and in-vitro (physicochemical) assays. Each of these assays has application in the control of biological products. Regardless of the type of quantitative assay employed, it is desirable and, in some cases, necessary, to use a biomimetic assay.

**Animal Model Assays**—Biomimetic assays in animal models have been developed for routine use. Although these assays have a relatively long history of use, they have several major disadvantages such as the large number of animals and appropriate animal facilities and handlers required, the high cost of analysis, the long analysis time (i.e., several days to weeks), and poor reproducibility of results. They are, however, in use mainly because a cell culture-based or in-vitro assay has not been developed and demonstrated to be of equal or greater value. An example of such an assay is that used for the determination of the activity of human growth hormone (somatrem and somatropin). The potency of human growth hormone is determined with a rat weight gain bioassay. Hypophysectomized female rats are monitored for weight gain over an 11-day period after daily injections with human growth hormone. The relative potency of the test sample is obtained by statistical comparison of the activity of the sample to that of a reference material/reference standard. Animal models can be used as bioidentity tests if and when appropriate in-vitro biological and/or physicochemical assays are developed for the measurement of potency of products.

**Cell Culture-Based Bioassays**—This group of assays is comparatively easier to perform, gives results faster (1 to 3 days), and is considerably less expensive and less wasteful of resources than the animal model assays. Cell culture-based bioassays provide information on the effect of the biological product in a living system, but they are imprecise as a consequence of the variances of living cells but not as imprecise as an animal model assay. However, they can be automated and therefore can be repeated sufficiently to provide relatively reproducible and accurate results. An example of this type of assay is the measurement of antiviral activity of human  $\alpha$ -interferon in a human diploid foreskin cell line or in a human lung carcinoma cell line (A549). This assay is performed in microtitration plates by incubation of cells with  $\alpha$ -interferon and subsequent challenge with encephalomyocarditis virus. The cells that survive are detected by dye binding and the dilution of  $\alpha$ -interferon where 50% protection of the monolayer occurs is calculated.

**In Vitro (Physicochemical) Assays**—This group of assays does not rely on a living model, but is usually based on the chemical action of a biological product. These methods are comparatively simple, fast, precise, and accurate. The activity of tissue-type plasminogen activator (alteplase), for example, can be determined with an in vitro clot lysis assay that can be automated and can provide the required results within hours. A synthetic fibrin clot is formed in the presence of plasminogen as a result of the action of the enzyme thrombin on fibrinogen. When alteplase is added, the plasminogen is converted to the active enzyme plasmin, which then lyses the synthetic clot. The assay endpoint is followed spectrophotometrically or visually by noting the release of entrapped air bubbles. Another advantage of this type of assay, because of its precision and accuracy, is that it can be used to provide reliable estimates of the stability of the product. Examples of antibody:antigen and protein:ligand (receptor)-based in-vitro bioassays have also been developed for specific applications. These types of assays offer many advantages in their application to determine the potency of monoclonal antibodies or other highly ligand-specific proteins whose reactivity includes a binding step.

## dna determination

Residual host cell DNA is a potential process-specific impurity in a biotechnology-derived product. The residual DNA is unique for each product because it is dependent on the host organism and the process recovery procedure used to manufacture the product. Although adverse health effects have not been reported from biologicals because of their DNA content, regulatory agencies have requested manufacturers to ensure that the DNA level in biotechnology-derived products is reduced to low levels.

The technique of DNA hybridization (dot blot analysis) is the most sensitive, routine DNA assay available to determine the DNA content of products. It is valuable as a purification process assay to demonstrate that a low level of DNA has been attained early in the manufacturing process. The method relies on the hybridization of cellular DNA from the sample with either specific 32P-labeled or chemically modified DNA probes obtained from the DNA of the host cell. The analysis is performed by first isolating any residual DNA in the sample by a procedure that may include hydrolysis of the protein, chromatography, organic extractions, and alcohol precipitation. The isolated DNA is denatured and then applied to a nitrocellulose or nylon membrane along with a set of serially-diluted host DNA standards. Positive and negative DNA controls are also applied and the membrane may be baked at approximately 80° or placed under UV light to complete binding of the DNA to the membrane. A DNA probe is then prepared either by nick translation, random primer synthesis, or chemical modification of a DNA extract of the host cell. The DNA probe is purified and thermally denatured at 95°. It is then added to the baked or UV-treated membrane and allowed to hybridize with the DNA of the samples at approximately 42° in the presence of formamide or at higher temperatures without formamide for 24 to 48 hours. The membrane is subsequently placed between two X-ray films and exposed to produce an autoradiograph or is developed by immunochemical means using an enzyme conjugate/substrate system similar to ELISA and/or Western blot. The DNA of the sample is estimated by visual comparison of the dot intensity of the sample to those of the diluted DNA standards. The autoradiogram can also be scanned by optical densitometry. The sensitivity of the assay, i.e., 10 to 250 pg, is determined by the limit of visual detection above background of the

serially-diluted DNA standards.

Other methods for DNA determination have been developed using biosensor technology. This methodology currently determines total DNA/nucleic acid impurities rather than specific host cell DNA. This technology may become quite valuable in the future, especially when more specific DNA binding methods are developed. Finally, the recently developed polymerase chain reaction (PCR) technology, which involves DNA amplification, may prove useful in detection and identification of contaminant DNA. Quantitative use of this technology, however, will require further development.

#### carbohydrate determination

One of the possible post-translational modifications that occurs on proteins is the covalent attachment of oligosaccharide chains. Glycosylation is a characteristic of recombinant proteins that are expressed from eukaryotic cell lines. Although the polypeptide chain of a glycoprotein is synthesized under the direct control of the genetic code, oligosaccharides are not primary gene products, but are synthesized by enzymes known as glycosyltransferases. This synthesis results in microheterogeneity of the carbohydrate chains. Also, glycosylation is cell-line dependent, so glycoproteins with identical polypeptide chains made in different cell lines may have considerably different carbohydrate structures. The sugars commonly found in glycoproteins include neutral sugars (d-galactose, d-mannose, and L-fucose), amino sugars (N-acetylglucosamine and N-acetylgalactosamine), and the acidic sugar, sialic acid.

Two main approaches can be taken to determine the sugars covalently attached to the glycoprotein. Both are based on the understanding that microheterogeneity is a common phenomenon among glycoproteins, and that the information represents either average composition or representative structures.

The first approach is the determination of the composition of sugars in a glycoprotein, which can be performed by several methods. Neutral sugars and sialic acid may be determined by simple colorimetric tests. Total neutral sugars can be determined following reaction with phenol and sulfuric acid and measuring the absorbance of the solution at about 490 nm compared to a standard curve. Following mild acid hydrolysis and periodate oxidation, free sialic acid content can be determined with thiobarbituric acid and the absorbance of the solution at about 550 nm compared to a standard curve. Individual neutral sugars can be determined following acid hydrolysis by several methods. Underivatized, they can be separated by HPIEC at high pH and quantitated by pulsed amperometric detection. They may also be converted to the alditol peracetates with acetic anhydride or to the aldononitrile acetates with hydroxylamine hydrochloride and pyridine prior to peracetylation, and the derivatives separated by gas chromatography.

The second approach in determining the carbohydrate composition is to release and separate individual oligosaccharide structures covalently attached to the glycoprotein. This requires an understanding of the types of structures attached. The attachment of sugars to proteins can occur in two major ways: through an O-glycosidic bond involving the hydroxy group of serine, threonine, or modified amino acids such as hydroxylysine or hydroxyproline, or through the N-glycosidic bond of asparagine. O-linked oligosaccharides can be released from the protein following beta-elimination under alkaline conditions and reduction of the reducing end sugar with sodium borohydride. N-linked oligosaccharides can be released chemically by hydrazinolysis or enzymatically by one of a variety of specific glycosidases, such as endo H, endo F, or peptid-N-glycanase. The oligosaccharides can then be separated by HPIEC at high pH and quantitated with pulsed amperometric detection. This results in an oligosaccharide or carbohydrate map analogous to the peptide map for the protein.

#### adventitious and endogenous agent detection

Specific assays pertaining to biotechnology focus on the detection of bacteria, fungi, mycoplasma, and viruses. These reflect the possible contaminants that may occur in both bacterial fermentation and mammalian cell culture. Control is exerted in a variety of ways including characterization of the master seed bank and the working cell banks to ensure freedom from these contaminants, evaluation of raw materials, the design and operation of closed manufacturing systems, testing of production lots, and validation of specific manufacturing processes to ensure that contaminants would be inactivated or removed if present.

Freedom of final sterile dosage forms from bacteria and fungi is usually evaluated by tests for sterility as described in [Sterility Tests](#) (71). Mycoplasma assays are performed by standard cultivation methods employing aerobic and anaerobic incubation of solid medium in plates and semisolid broth in tubes and must comply with the code of federal regulations (21 CFR 610.12). In addition, noncultivable mycoplasma are detected microscopically by using the Hoechst bisbenzimide staining method.

Various methods that are used for the detection of adventitious virus contamination in cell lines include inoculation of indicator cell lines selected for their ability to support the replication of a broad range of viruses and monitoring these for markers of virus infection such as cytopathology, hemadsorption, hemagglutination, and immunofluorescence; inoculation of intact animals and monitoring for illness and death; inoculation of animals and, after four weeks, collection and evaluation of serum for antibodies to specific viruses of concern; and specific immunologic assays or genetic probes for some viruses of concern that cannot be detected by the other methods listed.

The expression of endogenous retrovirus genes is highly variable among different mammalian cells and cell lines. The unpredictable nature of their expression and the diversity of their biochemical and biological properties preclude the use of a single test and instead require an integrated testing strategy. Test methods generally used include transmission electron microscopy of cells from the master seed bank and ultracentrifuged pellets of cell-free, cell culture harvests; various assays for infectious retroviruses that use retrovirus-susceptible indicator cell lines; reverse transcriptase activity; and induction of retroviruses in cells of the master cell bank with chemicals known to induce retroviruses. In addition to classical virological methods, newer techniques such as molecular probe hybridization are also beginning to be used for these evaluations.

## 1046 CELL AND GENE THERAPY PRODUCTS

### INTRODUCTION

#### General Definitions

Recent advances in biotechnology have resulted in the development of two new categories of products—cell therapy products and gene therapy products. Cell therapy products contain living mammalian cells as one of their active ingredients, while gene therapy products contain pieces of nucleic acid, usually deoxyribonucleic acid (DNA), as one of their active ingredients. Some products combine both categories, resulting in a therapy that uses cells that express a new gene product. Both cell and gene therapy products may be combined with synthetic or natural biomaterials to form tissue constructs.

For the purpose of this chapter, cell and gene therapy products include any product that has live cells or pieces of nucleic acid, however formulated. The following are excluded at this time: (1) tissue-based products in which the cells are removed or killed, (2) enhanced reproductive methods such as in vitro fertilization, (3) non-mammalian cell-based products, (4) traditional vaccines such as live attenuated virus, and (5) noncell, nongene products manufactured by using cells or recombinant-DNA (rDNA) technology, which are discussed under

[Biotechnology-Derived Articles](#) (1045).

Cell Therapy Products

Cell therapy products are products with live cells that replace, augment, or modify the function of a patient's cells that are diseased, dysfunctional, or missing. Transplantation of bone marrow to replace marrow that has been destroyed by chemotherapy and radiation is an example of a cell-therapy product. These products are also referred to as somatic cell therapy products because nongerm-line cells are used in the product. In addition, cells may be combined with biomaterials. For example, dermal or epidermal cells can be grown on a collagen substrate to produce a sheet of cells for wound and burn therapy. Examples of cell therapy products are shown in [Table 1](#).

Table 1. Examples of Cell Therapy Products

Indication	Product
Bone marrow transplantation	Devices and reagents to propagate stem and progenitor cells, to select stem and progenitor cells, or to remove diseased (cancerous) cells
Cancer	T cells, dendritic cells, or macrophages exposed to cancer-specific peptides to elicit an immune response
	Autologous or allogeneic cancer cells injected with a cytokine and irradiated to elicit an immune response
Pain	Cells secreting endorphins or catecholamines (encapsulated in a hollow fiber)
Diabetes	Encapsulated $\beta$ -islet cells secreting insulin in response to glucose levels
Wound healing	Sheet of autologous keratinocytes or allogeneic dermal fibroblasts on a biocompatible matrix
	Sheet of allogeneic keratinocytes layered on a sheet of dermal fibroblasts
Tissue repair	
Focal defects in knee cartilage	Autologous chondrocytes
Cartilage-derived structures	Autologous or allogeneic chondrocytes in a biocompatible matrix
Bone repair	Mesenchymal stem cells in a biocompatible matrix
Neurodegenerative diseases	Allogeneic or xenogeneic neuronal cells
Liver assist (temporary; for bridging until liver transplant or recovery)	Allogeneic or xenogeneic hepatocytes in an extracorporeal hollow fiber system
Infectious disease	Activated T cells

There are three sources of donor cells for cell therapy products: (1) the patient's own cells (autologous cell products), (2) the cells from another human being (allogeneic cell products), and (3) the cells derived from animals such as pigs, primates, or cows (xenogeneic cell products). Autologous cells are not rejected by the patient, but they are not available for many treatments because they are missing, dysfunctional, or diseased. In those situations allogeneic and xenogeneic cells can be used. The advantage of allogeneic cells is that they do not trigger a rejection reaction as strong as that caused by xenogeneic cells. Xenogeneic cells are used when human cells with the desired characteristics are not available or the supply of human donors is too limited. Cell therapy products are sometimes encapsulated in a device that prevents the patient's cells and antibodies from killing the xenogeneic cells. However, the use of xenogeneic cells has the potential to cause zoonoses in humans. Much research is focused on identifying and propagating stem cells, regardless of the source, because stem cells can be manipulated to differentiate either during manufacturing or after administration. Cell lines are preferable to freshly isolated cells because they can be tested extensively for viruses, tumorigenicity, and other features. They also ensure a constant and reproducible product by minimizing donor-to-donor variability.

Cell therapy products can be modified by treatment with DNA or another nucleic acid so that the pattern of gene expression is changed. This new product, a combination of gene therapy and cell therapy, is referred to as an *ex vivo* gene therapy product. Typically, cells are taken from the patient and modified outside of the body before they are returned to the patient.

Cell therapy products face several unique manufacturing challenges that are addressed in other sections of this chapter. First, cells cannot be terminally sterilized or filtered so removal or inactivation of microorganisms or viruses without killing the cells is problematic. Second, every raw material used in manufacturing has the potential of remaining associated with the cells. Qualification and sourcing of all raw materials is critical to producing a safe and effective product. Third, storage of the cell therapy products may present a challenge. Freezing is the main mode of long-term storage, and some cell therapy products cannot be frozen without changing their basic characteristics, especially those for differentiated functions. These types of products may have to be administered to patients within hours, or days at the most, after completion of the manufacturing process. Fourth, there is often an urgent clinical need to administer a product as soon as possible. Fifth, some products consist of a batch size equivalent to one dose, very often in a small volume. For these last three challenges, traditional analytical methods, especially those for sterility, mycoplasma, and potency, are not always applicable because these methods are not rapid or they are not amenable to small volumes. Even when these traditional methods are performed, the results are not available in time for products requiring rapid release. These products are often released on the basis of the results of new, very rapid or small-volume methods. Currently there are no compendial standards for such methods, although, as stated in the General Notices and 21 CFR 610.9, alternative methods to compendial tests are permissible, provided they are shown to be equivalent. As such new methodologies become properly validated, they will be included in the compendia.

#### Gene Therapy Products

Gene therapy products are products in which nucleic acids are used to modify the genetic material of cells. A retroviral vector used to deliver the gene for factor IX to cells of patients with hemophilia B is an example of a gene therapy product. Gene therapy products can be broadly classified on the basis of their delivery system. Means for delivering gene therapy products include viral vectors (viruses with the genes of interest but usually without the mechanism to self-replicate *in vivo*), nucleic acids in a simple formulation (naked DNA), or nucleic acids formulated with agents, such as liposomes, that enhance their ability to penetrate the cell. Some types of gene therapy block the expression of a gene by the administration of antisense oligonucleotides, which are complementary to a naturally occurring ribonucleic acid (RNA) and block its expression. Most of the initial clinical work has been done using viral vectors. The choice of a gene vector is complex (see Design Considerations for Gene Vectors under Manufacturing of Gene Therapy Products). The most common viruses used to date include murine retroviruses, human adenovirus, and human adeno-associated viruses (AAVs). Antisense-oligonucleotide products are in clinical development and on the market. Examples of gene therapy products are shown in [Table 2](#).

Table 2. Examples of Gene Therapy Products

Categories or Strategies	Indication: Administered Product
Gene replacement	
Short term	Cardiovascular disease: growth factor vector on a biocompatible scaffold <sup>1</sup>
Long term	Cystic fibrosis: transmembrane conductance regulatory vector
	Hemophilia: factor VIII or IX vector
Immunotherapy	Cancer or arthritis: autologous tumor cells or lymphocytes, respectively, transduced with cytokine genes
Conditionally lethal genes <sup>2</sup>	Cancer (solid tumor): thymidine kinase (TK) or cytosine deaminase (CD) vector into tumor cells
	Graft versus host disease (GVHD): TK or CD vector transduced into donor T cells
Antisense	Cancer: anti-oncogene vector
	Cytomegalovirus retinitis: antiviral vector
Ribozyme	Human immunodeficiency virus (HIV): antiviral ribozyme vector into autologous lymphocytes
Intrabodies	Cancer or HIV: single-chain antibody to a tumor protein or a viral protein, respectively

1. This product promotes formation of new blood vessels.

2. Cells with conditionally lethal genes as well as their neighboring cells are killed after the administration of a second drug *in vivo*. For TK, the drug is gancyclovir. For CD, the drug is

fluorcytosine.

Although manufacturing of vectors or nucleic acids can be analogous to that used for rDNA products or vaccines, there are some unique challenges. Analytical methodologies for vectors (see Analytical Methodologies) are still being developed. Methods for quantitating viral vector particles and determining the number of particles that are active (potent) are important areas that are rapidly evolving. Traditional assays for viral dose, such as the plaque assay or the tissue culture infectious dose assay, detect a fraction of the active vector particles. The precision of such assays is about a factor of three (half a log). Further, manufacture of large batches of viral vectors with no, or minimal amounts, of replication-competent viruses (RCVs) is challenging. Detecting a small number of RCV particles in the presence of large amounts of replication-defective vector is difficult. As in cell therapy products, sourcing of raw materials is critical. Removal of adventitious agents or other process contaminants from viral vectors can be impossible. Even defining purity is an issue for enveloped viral vectors, such as retroviruses or herpes viruses, as they incorporate cellular proteins in their envelope when they bud from the cell. This makes it difficult to determine if contaminating extracellular cellular proteins have been adequately removed.

For gene therapy vectors administered directly to patients, there are safety concerns related to the fate of their nucleic acids. For example, alteration of germ-line DNA is undesirable. Integration of gene therapy products into somatic cell DNA carries a theoretical risk of insertional mutation, which could result in modified gene expression and deregulation of the cell. For viral gene therapies, patients may need to be monitored for the presence of RCV. To address the risks associated with specific products, preclinical studies, quality control (QC) testing, and patient monitoring strategies need to be developed in accordance with the applicable regulations and guidance documents. The methodologies used to support these activities, including polymerase chain reaction (PCR) methods, are amenable to compendial standardization.

#### Chapter Purpose and Organization

Clinical uses for cell and gene therapy products, their manufacturing processes, and analytical schemes for determining identity, dose, potency, purity, and safety are rapidly evolving and are as diverse as the products themselves. This informational chapter summarizes the issues and best current practices in the manufacturing, testing, and administration of cell and gene therapy products. Usually informational chapters focus on materials that are already commercially available. This chapter, however, not only discusses products for commercial applications, but it also addresses the production of clinical trial materials and the other unregulated uses, such as bone marrow transplantation. When different approaches can be used for clinical trial material as compared to those used for commercial product, it is so stated.

The traditional compendial perspective is to develop public standards that can be applied to a particular final product without expressly defining production details. Efforts have been made in this chapter to specify when traditional methodologies or standards can be adapted. Novel methodologies applicable to cell and gene therapies are also highlighted. As these new methodologies become properly validated, they will be included in subsequent publications.

This chapter is extensive because of the diverse nature of the products and the special considerations that they require. Manufacturing has been divided into three sections. The first section, Manufacturing Overview, discusses general aspects of manufacturing and process development. The other two manufacturing sections are Manufacturing of Cell Therapy Products and Manufacturing of Gene Therapy Products. The latter section includes a subsection on designing gene vectors. On-Site Preparation and Administration follows the manufacturing sections because the handling of these products at the clinic often requires facilities and expertise not found in a typical hospital. Storage, shipping, and labeling issues are addressed under Storage and Shipping and under Labeling. Regulations, Standards, and New Methodologies summarizes existing guidelines and highlights the need for the development and validation of new methodologies to assess product quality. The final sections of this chapter, Definition of Terms and Abbreviations, list and define the terms and abbreviations referred to in this chapter and those commonly employed in this field.

## MANUFACTURING OVERVIEW

### Introduction

The manufacturing of cell and gene therapy products has been divided into three sections. This section, Manufacturing Overview, discusses five topics that apply to manufacturing of all cell and gene therapy products: (1) raw materials, (2) characterization of banked materials, (3) in-process controls, (4) specifications, and (5) validation considerations. Manufacturing of Cell Therapy Products addresses the manufacturing of cell therapy products including cell products into which genetic material has been introduced. Manufacturing of Gene Therapy Products addresses the manufacturing of gene therapy vectors, both viral and nonviral, discussing the design of gene vectors in detail.

All the general principles of current good manufacturing practice (CGMP) as outlined by the FDA in 21 CFR 210, 21 CFR 211, 21 CFR 600s (especially 21 CFR 610), 21 CFR 820, and discussed in USP informational chapters, such as [Biotechnology-Derived Articles](#) (1045), apply to the manufacturing of cell and gene therapy products. The manufacturing facility, equipment and process, raw materials, quality systems, and trained personnel are some of the key elements of CGMP. CGMPs apply throughout the clinical development to both the manufacturing process and facility. The extent of control increases as clinical development progresses, with full CGMP compliance expected by initiation of Phase III of the pivotal clinical trial(s). The facility should be carefully designed, built, and validated to accommodate the unique features of the product's manufacturing process. Equipment should be robust, provide consistent product, and allow periodic calibration. Critical equipment, such as incubators and freezers, needs to be fitted with alarm systems that can remotely signal failure. Quality control (QC) and quality assurance (QA) programs should exert control over the manufacturing facilities, the manufacturing process, the validation efforts, and all testing of the raw materials, in-process material, bulk product, and final formulated product. Training and certification programs are central to maintaining a technically competent manufacturing staff. A documentation program should be implemented to support all manufacturing, training, and quality operations. Changes to processes and procedures should follow a formal program based on well-established CGMP and ISO change control principles.

### Raw Materials

#### types of raw materials

A wide variety of raw materials may be used in manufacturing. They may include relatively simple materials or complex substances, such as cells, tissues, biological fluids, polymeric matrices, mechanical supports, hydrogels, culture media, buffers, growth factors, cytokines, cultivation and processing components, monoclonal antibodies, and cell separation devices. These materials may remain in the final therapeutic product as active substances or as excipients. They may also be used in the manufacturing process as ancillary products. Ancillary products are components or substances that exert an effect on a therapeutic substance (for example, a cytokine may activate a population of cells). However, the mode of action of the ancillary product is limited to the interaction with the therapeutic entity, and the ancillary product is not intended to be present in the final therapeutic product. "Feeder cells," which are used to provide nutrients or growth factors for the product cell, are an example of an ancillary product. The quality of raw materials used in the production of a cell or gene therapy product can affect the safety, potency, and purity of the product. Therefore, qualification of raw materials is necessary to ensure the consistency and quality of all cell and gene therapy products.

#### qualification

It is the responsibility of the manufacturer of the product to ensure that all raw materials used in manufacturing are appropriately qualified. Qualification is the process of acquiring and evaluating data to establish the source, identity, purity, biological safety, and overall suitability of a specific raw material so as to ensure the quality of all raw materials used in the manufacturing process. The broad natures of the cell and gene therapy products and of the materials used to produce these products make it difficult to recommend specific tests or protocols for a qualification program. Therefore, rational and scientifically sound programs must be developed for each raw material.

Activities involved with raw material qualification will change as products move through various stages from clinical trials to licensure and commercialization. A well-designed qualification program becomes more comprehensive as product development progresses. In the early stages of product development, safety concerns are a focus in a raw material

lification plan. In the later stages, raw material qualification activities should be completely developed and should comply with CGMP. Ultimately, each raw material employed in the manufacture of a cell or gene therapy product should be produced under conditions that are in compliance with CGMP. On rare occasions, complex or unique substances that have been shown to be essential for process control or production may not be available from suppliers that produce them in compliance with CGMP. In these situations, the cell or gene therapy product manufacturer will have to develop a scientifically sound strategy for qualifying the raw material.

A qualification program for raw materials used in cell and gene therapy manufacturing should address each of the following areas: (1) identification and selection, (2) suitability for use in manufacturing, (3) characterization, (4) fetal bovine serum, and (5) quality assurance.

**Identification and Selection**— In the early stages of product development, important decisions regarding the types of raw materials to be employed in the manufacture must be made. As manufacturing progresses and products mature, certain materials that are deemed necessary at this point may turn out to be impossible or prohibitively expensive to qualify. Attention must be paid to issues such as suitability, toxicity, availability, consistency, contamination, and traceability. Raw materials that could be difficult to qualify may have to be investigated and identified in the early stages of product development.

Every material employed in the manufacturing process should be accounted for. The source and intended use for each material should be established, and the necessary quantity or concentration of each material used should be determined. Primary sources, and when possible secondary sources, for each material should be identified. In all cases, suppliers should provide information regarding the traceability of each material, especially for human- and animal-derived raw materials. For instance, human serum albumin and processed allogeneic non-A,B human serum require donor infectious disease status information prior to use, and a material such as fetal bovine serum (FBS) requires herd qualification and country of origin certification before being used in a manufacturing process (see Fetal Bovine Serum).

**Suitability**— An assessment of the suitability of each raw material used in manufacturing is necessary in order to ascertain the risk that the raw material may pose to the safety, potency, and purity of the final therapeutic product. Knowing the source and the processes employed in the manufacture of each raw material will help determine the relative level of risk for each item. The quantity of the material and its point of introduction in the manufacturing process also affect the risk profile of a raw material. Materials that may have toxic effects or raise biological safety concerns receive special attention. Such materials should be subjected to extensive testing prior to use or should be monitored in the final product. Validation studies that demonstrate that such materials are effectively and consistently removed or rendered inactive in the course of manufacturing will also be necessary for eventual licensure of each product. The biocompatibility of natural or synthetic biomaterials used in cell therapy products may be assessed by subjecting the material to the testing protocols outlined in the FDA's Blue Book Memorandum (May 1, 1995), which is a modification of the ISO document 10993-1:1997 entitled "Biological Evaluation of Medical Devices—Part 1: Evaluation and Testing". USP chapters [Biological Reactivity Tests, In Vitro](#) (87) and [Biological Reactivity Tests, In Vivo](#) (88) should also be consulted.

**Characterization**— Once the suitability of each raw material employed in manufacture has been assessed, specific QC characterization tests need to be developed or implemented for each material. The test panel for each raw material should assess a variety of quality attributes, including identity, purity, functionality, freedom from adventitious or microbial contaminants, and suitability for intended use. The level of testing for each component is a product of its risk assessment profile and the knowledge gained about each component during development. Test specifications should be developed for each raw material to ensure consistency and performance of the manufacturing process. Acceptance criteria should be established and justified on the basis of the data obtained from lots used in preclinical and early clinical studies, lots used for demonstration of manufacturing consistency, and relevant development data, such as those arising from analytical procedures and stability studies.

Many raw materials, such as cells isolated from blood, serum-derived fluids and extracts, or growth factors, are biological in nature; therefore, they are highly complex and difficult to fully characterize. Tests for sterility, pyrogenicity, mycoplasma, and adventitious or infectious viral agents, including RCV, should be performed on these materials. The specific adventitious viral agent test panel is dependent on the source of the component and how that component is manufactured or prepared. Because these materials exert their effects through complex biological activities—and biochemical testing may not be predictive of process performance—functional or performance testing may be necessary. Performance variability of such materials may have a detrimental impact on the eventual potency of the final therapeutic product. Examples of complex functionality testing for raw materials are growth-promotion testing of individual lots of FBS on the cell line used in manufacturing, performance testing of digestive enzyme preparations, and *in vitro* tissue culture cytotoxicity assays.

**Fetal Bovine Serum**— One commonly employed animal-derived material in manufacturing is fetal bovine serum (FBS). FBS is often added to the cultivation medium to promote cellular proliferation of a wide variety of cell types, including cell cultures that are derived from primary tissue explants and biopsy specimens. Growth factors, hormones, and other nutritive components present in FBS, many of which are undefined or present in trace quantities, provide the necessary components required by many cells to survive and undergo cellular division *in vitro*. The production of high-titer gene therapy vectors from cell lines can also require rich culture medium that includes FBS at levels between 10% and 15%. Defined, serum-free media have been developed for a number of cell types. Although some cell lines may be gradually adapted to serum-free or low-serum culture conditions, this may not be possible for certain fastidious cells, thereby necessitating FBS use.

Although FBS use may be required, development and assessment of serum-free or reduced-serum culture media should be considered. A number of bovine-derived bacteria, mycoplasma, and viruses are known to be associated with FBS. These organisms could potentially enter the process stream and contaminate the final product. The potential risk of BSE, the bovine form of TSE (transmissible spongiform encephalopathy), transmission with this material has been the subject of international discussion. Although FBS has been categorized as a low-risk material, adequate testing and sourcing of FBS lots must be managed appropriately in a qualification program. Reduction or elimination of FBS in the manufacturing process can reduce the risks associated with contamination by adventitious agents.

FBS must be obtained from herds that are monitored for specific diseases relevant in agricultural settings (for example, tuberculosis or brucellosis) and that are from regions known to be free from BSE. Each lot must meet established guidelines for sterility and endotoxin content as well as freedom from specific bovine viruses. To increase the level of safety assurance, consideration should be given to employing methods, such as irradiation or nanofiltration, that remove or inactivate viral entities known to be associated with FBS.

It should be noted that defined media formulations typically include components, such as albumin and transferrin, that are purified from animal or human plasma. The purification, processing, and extensive testing of such components further minimize, but do not eliminate, the risk of viral or microbial contamination. Apart from the risks associated with adventitious agents, residual FBS in the final product may trigger an immune response in patients. The level of residual FBS in the final product does not necessarily correlate with the starting amount of FBS, and it can depend upon the nature of the product and the purification process. Even if FBS is not included in the manufacture of the product, residual amounts of other components used in the manufacturing process, including recombinant proteins or other defined media components, may be potentially antigenic.

**Quality Assurance**— The components of this part of the qualification program are multifaceted and should reflect those found in a typical manufacturing environment for a pharmaceutical product produced in compliance with CGMP. These activities should include the following systems or programs: (1) incoming receipt, segregation, inspection, and release of materials prior to use in manufacturing, (2) vendor auditing and certification, (3) certificate of analysis verification testing, (4) formal procedures and policies for out-of-specification materials, (5) stability testing, and (6) archival sample storage.

#### Characterization of Cell and Virus Banks

**Cell Banks**— A cell bank is a collection of vials containing cells stored under defined conditions, with uniform composition, and obtained from pooled cells derived from a single cell clone. The cell bank system usually consists of a master cell bank (MCB) and a working cell bank (WCB), although more tiers are possible. The MCB is produced in accordance with CGMP and preferably obtained from a qualified repository source (source free from adventitious agents) whose history is known and documented. The WCB is produced or derived by expanding one or more vials of the MCB. The WCB, or MCB in early trials, becomes the source of cells for every batch produced for human use. Cell bank systems contribute greatly to consistency of production of clinical or licensed product batches, because the starting cell material is always the same. Mammalian and bacterial cell sources are used for establishing cell bank systems.

**Virus Banks**— The master virus bank (MVB) is similar to the MCB in that it is derived from a single production run and is uniform in composition. The working virus bank (WVB) is derived directly from the MVB. As with the cell banks, the focus of virus bank usage is to have a consistent source of virus, shown to be free of adventitious agents, for use in production of clinical or product batches. In keeping with CGMP guidelines, testing of the cell bank to be used for production of the virus banks, including quality assurance testing, should be completed prior to the use of this cell bank for production of virus banks.

**Qualification**— Cell and viral bank characterization is an important step toward obtaining a uniform final product with lot-to-lot consistency and freedom from adventitious agents. Testing to qualify the MCB or MVB is performed once and can be done on an aliquot of the banked material or on cell cultures derived from the cell bank. Specifications for qualification of the MCB or MVB should be established. It is important to document the MCB and MVB history, the methods and reagents used to produce the bank, and the storage conditions. All the raw materials required for production of the banks, namely, media, sera, trypsin, and the like, must also be tested for adventitious agents.

**Qualifying Master Cell Bank**— Testing to qualify the MCB includes the following: (1) testing to demonstrate freedom from adventitious agents and endogenous viruses and (2) identity testing. The testing for adventitious agents may include tests for nonhost microbes, mycoplasma, bacteriophage, and viruses. Freedom from adventitious viruses should be demonstrated using both *in vitro* and *in vivo* virus tests, and appropriate species-specific tests such as the mouse antibody production (MAP) test. Identity testing of the cell bank should establish the properties of the cells and the stability of these properties during manufacture. Cell banks should be characterized with respect to cellular isoenzyme expression and cellular phenotype and genotype, which could include expression of a gene insert or presence of a gene-transfer vector. Suitable techniques, including restriction endonuclease mapping or nucleic acid sequencing, should be used to analyze the cell bank for vector copy number and the physical state of the vector (vector integrity and integration). The cell bank should also be characterized for the quality and quantity of the gene product produced.

**Qualifying Master Virus Bank**— Testing of the MVB is similar to that of the MCB and should include testing for freedom from adventitious agents in general (such as, bacteria, fungi, mycoplasma, or viruses) and for organisms specific to the production cell line, including RCV. Identity testing of the MVB should establish the properties of the virus and the stability of these properties during manufacture.

**Qualifying Working Cell or Virus Bank**— Characterization of the WCB or WVB is generally less extensive, requiring the following: (1) testing for freedom from adventitious agents that may have been introduced from the culture medium, (2) testing for RCV, if relevant, (3) routine identity tests to check for cell line cross-contamination, and (4) demonstration that aliquots can consistently be used for final product production.

#### In-Process Control

Manufacturing processes should have well-defined go–no go decision point criteria that are applied to key in-process intermediates and are used to pool material that has been processed through a step in several sublots. Quality must be built into the product, rather than tested during batch release. In-process controls are the assays or tests that are performed to ensure that the in-process intermediate is of sufficient quality and quantity to ensure manufacture of a quality final product. Examples of in-process controls are listed in [Table 3](#). The main reason for performing the in-process control is to ensure that the correct product with anticipated quality and yield is obtained. Intermediate in-process material that fails to satisfy the in-process control criteria should not be used for further manufacturing. This material may be reprocessed if there are procedures in place for such activities. The reprocessed material must satisfy the original in-process specifications before it can undergo further manufacturing. If several sublots are to be pooled for further processing, sublots that fail to satisfy the criteria should not be included in the pool, even if the pool containing these failed sublots would pass the in-process assay criteria.

Table 3. Examples of In-Process Control Applications

Type of Product	Attribute to Control
Cell therapy	Quantity and viability of cells after a key processing step
	Cell phenotype after a culture step
Viral gene therapy	Quantity and viability of cells during bioreactor culture
	Quantity of virus after virus culture
	Specific activity of virus in fractions after column chromatography
	Quantity of host-cell DNA in fractions after column chromatography
Nonviral gene therapy	Optical density or change in oxygen consumption during culture
	Amount and form of plasmid prior to culture harvesting
	Amount and form of plasmid after extraction steps
	Amount of pyrogen or endotoxin after extraction steps in plasmid pool
Antisense-oligonucleotide therapy	Purity from strand side-products after key extension steps
	Quantity in fractions after chromatography

During clinical development, assays for product quality and yield should be performed after most processing steps to determine which steps are critical and which assays are most sensitive to deviations in the process. The information from these runs is also used to set the criteria for the selected assays. In-process controls are performed for fully validated processes to ensure that the process continues to be under control. The results of these assays should be trended and actions should be taken to correct problems as they arise.

#### Specifications

Specifications for cell and gene therapy products should be chosen to confirm the quality of the product by testing to ensure the safety and efficacy of the product. Selected tests should be product-specific and should have appropriate acceptance criteria established to ensure that the product exhibits consistent quality parameters within acceptable levels of biological variation, loss of activity, physicochemical changes, or degradation throughout the product's shelf life. The development and setting of specifications for cell and gene products should follow the principles outlined in the International Conference on Harmonization (ICH) guidance entitled "Q6B Specifications: Test Procedures and Acceptance Criteria for Biotechnological/Biological Products".

Establishing specifications for a drug product is part of an overall manufacturing control strategy that includes control of raw materials, excipients, and cell and virus banks; in-process testing; process evaluation and validation; stability testing; and testing for consistency of lots. When combined, these elements provide assurance that the appropriate quality is maintained throughout the manufacture of the product.

Appropriate specifications are established on the basis of thorough characterization of the product during the development phase and an understanding of the process and its capability. Characterization should include measurements of the physicochemical properties, safety, purity, process and product-related impurities, potency, viability, sterility, and quantity. Specifications for each product should be developed from this information by applying appropriate statistical methods. The data should include lots used in preclinical and clinical studies and should also include assay and process validation data that can be correlated to safety and efficacy assessments. Specifications should allow for the inherent variabilities exhibited by the production process and by the assay. The traditional lot-release specifications that apply to biologics may have to be re-examined for these product types. For example, the general safety test stated in 21 CFR 610.11 is a lot-release requirement that has been deleted for cell therapies, because it exhibits little relevance for these products.

Specifications for the product are anchored by an appropriate reference standard for the product. The reference standard for the product ensures that the process, as measured by the release assays, does not change significantly over time. The reference standard is made from a lot that is produced under CGMP and passes all in-process and final release testing. In addition, this reference standard is subjected to an additional level of characterization that includes tests not normally performed for product release. The reference standard need not be stored at the same dose, formulation, or temperature as the product. However, the stability of this reference standard needs to be determined. The reference standard verifies that a test produces acceptable results (passes its system suitability tests). Alternatively, a specific assay standard (working standard) can be used. If so, in the test it should behave similarly to the reference standard. Changing to a new reference standard (lot) should include many tests, all of which are run side by side with the existing reference standard. The impact of any change in the properties of the new reference standard should be carefully evaluated before it is adopted. One option for a reference standard for a cell product with a short shelf life or for a patient-specific application can be a bank of normal donor cells of the appropriate cell type. This cell bank can be used to ensure that the manufacturing process is capable of making a consistent product.

Production of a safe and efficacious product involves establishing not only lot-release specifications but also specifications designed to maintain control of the manufacturing process and the final product. This includes in-process specifications (see In-Process Controls), raw material and excipient specifications (see Raw Materials), product-release specifications, and shelf-life specifications. Specifications should be established for acceptance of raw materials and excipients used in the final formulation of the product. In addition, tests should be performed at critical decision steps during manufacture or at points where data serve to confirm consistency of the process. In-process release specifications should be established for each control step. Heterogeneity can result from the manufacturing process or storage of the product. Therefore, the manufacturer should define the pattern of heterogeneity within the product and establish limits that will maintain the therapeutic efficacy and safety of the product.

In some cases, specifications may be established for lot release as well as for shelf life. As discussed in ICH guideline Q5C, presented under [Quality of Biotechnological Products: Stability Testing of Biotechnological/Biological Products](#) (1049), the use of different specifications should be supported by sufficient data to demonstrate that the clinical performance

not affected. Acceptance criteria should be established and justified on the basis of data obtained from lots used in preclinical and clinical studies and lots used for demonstration, manufacturing consistency and on the basis of relevant development data, such as those arising from validated analytical procedures and stability studies. Acceptance criteria should also be correlated with safety and efficacy assessments.

Once specifications have been established, test results should be trended. Results that are out of specification (OOS), or even those that are out of trend, need to be investigated prior to dispositioning of the material. The purpose of an investigation is to determine the cause of the discordant result. The FDA's Draft Guidance for Industry: Investigating Out of Specification (OOS) Test Results for Pharmaceutical Production provides a systematic approach for conducting an investigation. An assay result can be rejected if it can be confirmed that an error, such as an analyst error, calculation error, or equipment failure, has taken place. If the investigation concludes that the product is not within the specification, the lot should be rejected. In unique situations, a product that does not meet all specifications may have to be administered to a patient. However, procedures must be in place to govern the communication of the OOS results to the physician or to the person responsible for making the decision to use the product and to provide instruction for any follow-up testing, patient monitoring, and communication of those results.

#### Considerations for Validation

The potential for wide biological variation in cell and gene therapy products, particularly for patient-specific treatments, affects the validation effort. Nevertheless, the basic principles of process validation for any biological product, including those recommended by the ICH and FDA guidance documents and recommended under [Validation of Compendial Procedures](#)

([1225](#)) and [Validation of Microbial Recovery from Pharmacopeial Articles](#) ([1227](#)), apply to the validation of most cell and gene therapy products. Guidelines for validating viral vaccines can be relevant to gene therapy processes that produce viral vectors. The hold steps in a manufacturing process should be validated to ensure that in-process intermediates are within specification and that the final product can be formulated successfully. Any assay used during the process validation must itself be validated before the process validation is commenced.

Process validation for patient-specific products, such as autologous cell therapy products or custom gene therapy products, presents some unique issues. First, the starting materials for patient-specific products typically arise from patient-derived materials, such as biopsy material or apheresis cell products. The process should be designed to accept a wide range in the quality and quantity of starting material. Sometimes use of alternative procedures with additional steps are required when the starting material is of poor quality or below specified amounts. Validation should confirm that these alternative procedures still result in a final product that satisfies release specifications. Procedures should also be in place to deal with receipt of substantially more of the starting material than normally expected. Such procedures should address the disposition of the extra material. Second, manual processing of cells and tissues will exhibit a degree of inherent variability. It is essential to develop processing steps that will successfully and consistently result in appropriate process components and final product, even if the process is confronted with nonstandard or variable tissue materials, such as a T-cell suspension contaminated with red blood cells or low-weight biopsy material. Process validation should take this variability into consideration and ensure that critical manufacturing and testing endpoints consistently meet specifications. The process validation shows that the procedures can produce a product free of microbial contamination. It should also show that there is no cross-contamination among different patient product lots. If possible, the process should be validated for virus clearance as discussed in ICH Q5A: Viral safety evaluation of biotechnology products derived from cell lines of human or animal origin. If this is not possible, cells used for production of the product should be evaluated for their ability to propagate viruses that are known to contaminate these cells or source materials. This should include raw materials used as ancillary products.

As a result of the variability discussed above, the consistency and the robustness of the manufacturing process need to be assessed by testing more than three lots. It is not expected that every manufacturing effort will be successful for patient-specific therapies. However, the success rate should be established and tracked so as to discover any decrease in that rate and to take actions to correct the problem. Well-characterized banked primary cells may be used in the validation of the process if the donors have a range of profiles expected for the patient population to which the therapy will ultimately be directed. Trending of a number of statistically acceptable product administrations can also be appropriate.

### MANUFACTURING OF CELL THERAPY PRODUCTS

#### Introduction

Cell processing for cell therapy applications is a unique form of biologics manufacturing that relies on maintenance of stringent work practices designed to ensure product consistency and prevent contamination by microorganisms or by another patient's cells. Hallmarks of this unique form of manufacturing can include products with limited shelf lives, the need for rigorous control during manual processing steps, a manufacturing environment in which many product lots are simultaneously processed and assembled, raw materials that may or may not be part of the final product, and numerous pieces of processing equipment. By its very nature, cell processing requires a number of operations and manipulations by individuals well trained in aseptic processing techniques. The technical competence of the personnel is particularly crucial to product safety and efficacy with this form of manufacturing. Procedures involving lot segregation, line clearance, and operational discipline must be developed to decrease the chance of mix-up of patient-specific lots.

The degree of control required for cell processing operations is highly dependent upon a number of factors, including the complexity of an aseptic manufacturing process, the primary site of manufacturing, and the mode of administration of the cell product to the patient. Manufacturing processes that involve open manipulation of the cells even in a biological safety cabinet are at greater risk of contamination than the processes done in closed bioreactors or intravenous transfer bag systems that use sterile connection devices and tube-sealing devices. Clean rooms and biological safety cabinets are essential components for processes that involve open manipulations or for patient-specific products. The controlled environment of a carefully designed, constructed, validated, and maintained clean room will minimize the risks of environmental contamination during aseptic processing and decrease the possibility of cross-contamination of patient-specific products. Processes that utilize closed systems do not require clean room environments.

#### Procurement of Source Material

A variety of human- and animal-derived tissues, which can also include whole organs, serve as sources of cells for cell therapy products. Examples include skin, muscle, cartilage, bone, neural tissue, bone marrow, blood vessels, parenchymal cells from organs such as the liver, pancreas, and adrenal glands, and stem cells from adult and fetal tissues. A few general principles in the sourcing of these tissues are as follows: (1) systems must be developed so as to allow the material to be traced back to the donor; (2) steps must be taken to prevent the transmission of an infectious disease from the donor to the recipient; and (3) adherence to aseptic procedures during procurement and initial processing are necessary to ensure the safety of the final product because terminal sterilization of cells is not possible.

#### human tissue

Human-derived tissues may be sourced from normal healthy donors, cadaveric donors, or diseased patients, such as those with cancer. Applicable guidelines and standards for the procurement of human tissue are available from the American Association of Tissue Banks (AATB) and the FDA. Additionally, the federal policy in 45 CFR Part 46 is applicable to all federal or federally supported research. This policy requires that a certified institutional review board review and approve use of any tissue taken from a live human donor. The policy also includes special considerations for research on prisoners, children, and pregnant women or research in other areas involving gestational tissue. In all cases, appropriate written consent must be obtained from the donor or the donor's next of kin, describing which tissue is being procured and for what use it is intended. The donor must meet established guidelines for donor suitability and be tested for the infectious diseases listed in [Table 4](#). The medical history of the donor must be reviewed to ensure the absence of signs and symptoms of these diseases and to rule out issues and behaviors that increase the risk of exposure to such diseases.

Human tissue should be obtained under environmental conditions and controls that provide a high degree of assurance for aseptic recovery. Standard hospital operating room practices are applicable for tissues requiring dissection and surgical procurement. The air quality provided in a typical limited-access operating room is adequate for such procedures. Procurement personnel must be appropriately trained in all aspects of tissue recovery, such as surgical scrubbing, gowning, operating room behavior, anatomy, surgical site preparation, and antisepsis. Special care is required when tissue or organ procurement requires extensive manipulation of the bowel and when sharp dissection may result in the inadvertent puncture of the bowel. Tissue that contains microbial flora (for instance, skin) at the time of procurement can be adequately disinfected by using antimicrobial or bactericidal agents and extensive scrubbing.

Table 4. Infectious Disease Testing for Human Cells and Tissues Used in Cell Therapy Products

Cell Type	Testing:					
	HIV 1, 2	Hepatitis C	Hepatitis B	HTLV	Cytomegalovirus	Treponema pallidum
Autologous stem cells	R	R	R	R		

ther autologous tissue	R	R	R			
Allogeneic stem cells from family-related donors	X	X	X	X	X	X
Other allogeneic tissue	X	X	X	X	X	X

X—required

R—recommended; the labeling stating “tested negative” or “not tested for biohazards” may be required

\* For autologous or allogeneic cord blood donors or fetal tissue, a mother’s sample may be used for testing.

#### human blood and bone marrow

Hematopoietic progenitor cells represent one of the most extensively used cell sources in the field of human transplantation. These cells can be collected from the bone marrow, peripheral blood, placental umbilical cord blood, or fetal liver. The source of cells is somewhat dependent upon the patient, the disease, and the clinical protocol. Regardless of the cell source, methods for processing the cells are similar.

Human-derived blood cells and bone marrow cells may be sourced from normal, healthy donors or patients with hematological disorders. Applicable guidelines and standards for the collection and processing of these materials have been published by the American Association of Blood Banks (AABB), the Foundation for the Accreditation of Hematopoietic Cell Therapy, the National Marrow Donor Registry (NMDR), and the FDA. Similar issues regarding consent, infectious disease testing, and donor medical history apply in the sourcing of blood- or bone marrow-derived cells for allogeneic transplants. In cases where these cells will be subjected to selection, expansion, genetic manipulation, or other complex processing procedures, the testing outlined in [Table 4](#) should be followed.

Bone marrow for clinical use is harvested predominantly by percutaneous needle aspiration of the anterior or posterior iliac crests or the sternum. Standard hospital operating room practices are employed by specially trained personnel. Plastic syringes and commercially available aspiration needles are used to draw 3- to 5-mL volumes of marrow from each site of penetration. The material is transferred to a sterile, balanced salt solution or tissue culture medium containing sufficient anticoagulant, such as heparin, to prevent clotting. Removal of bone spicules may be accomplished by passing the material through stainless steel mesh screens or collection kits consisting of sterile, plastic collection bags with in-line filters having about a 200-µm porosity. The volume of marrow collected is dependent upon the body weights and other characteristics of both the donor and the recipient. The maximum volume to be harvested from a donor is about 10 to 15 mL per kg of body weight.

Circulating hematopoietic, peripheral blood progenitor cells (PBPCs) comprise a small population of peripheral blood mononuclear cells that can be utilized in place of or in addition to bone marrow. PBPCs are collected by apheresis, a procedure by which donor blood is withdrawn from a vein and separated ex vivo into some or all of its component parts. One or more of the components are retained as the harvest and the remaining parts are returned to the donor. Conditioning of the donor may enrich the number of circulating PBPCs in the harvest. Examples of such conditioning include collection during recovery from myelosuppressive chemotherapy and administration of hematopoietic growth factors, such as granulocyte colony-stimulating factor (G-CSF) and granulocyte–macrophage colony-stimulating factor (GM-CSF), or steroids. Collections are also improved by increasing the frequency or volume of apheresis. Apheresis requires one or two large-bore peripheral venous catheters in the upper extremities or a single large-bore, thick-walled, central venous double or triple lumen catheter (Mahurkur type). Two types of apheresis technology are available: the discontinuous-flow cell separators (Haemonetics) and the continuous-flow systems (COBE or Fenwall). Anticoagulation for normal to high flow rates is with a citrate-based material. In a closed system, the risk of contamination is low. The procedure is generally performed by trained, dedicated staff in a blood bank or in a donor center associated with a blood bank.

Placental and umbilical cord blood provides a third source of hematopoietic progenitor cells. Compared to bone marrow and PBPCs, the stem cells of placental and umbilical cord blood have a higher proliferative and self-renewal capacity. Volume of collection and thus cell number are limited and depend upon timing and the presence of a dedicated team of personnel. Collections are made during the third stage of labor. Typically, a closed method of collection is employed and involves cannulation or puncture of the umbilical vein with subsequent collection into plastic syringes or blood collection bags containing citrate-based anticoagulant. The procedure is performed in a controlled-access room away from the site of birth. Cellular content of the collection includes large numbers of erythrocytes, leukocytes, platelets, and target mononuclear cells. An open collection technique, which involves drainage of the blood by gravity from the cut end of the cord into sterile tubes containing anticoagulant, does not afford the same aseptic assurance level as the above-mentioned technique.

A major area of concern with the use of placental and umbilical cord blood relates to potential risks of unknown genetic disorders that may be transmitted to the recipient. Donor suitability is established by the usual infectious disease screening of the mother and the completion of a medical questionnaire. The donation remains anonymous and without any long-term follow-up of the child.

#### animal tissue

The major area of concern with the use of animal tissue relates to the known and unknown risks of potential infectious disease transmission to humans, and as such, the transplantation of animal cells raises unique public health concerns. Introduction of xenogeneic infectious agents into and propagation through the general human population is a risk that must be addressed. Draft Public Health Service (PHS) Guideline on Infectious Disease Issues in Xenotransplantation (August 1996), and any other related regulatory documents that are generated as this field advances, must be consulted when developing xenotransplant cell therapy products. Developers of such products should understand that the product recipients will be subjected to a high level of scrutiny (for instance, clinical and laboratory surveillance or registry in xenotransplantation databases) because of the above-mentioned public health concerns.

The use of animal tissue in the manufacture of cell therapy products requires that the tissue be sourced in a controlled and documented manner and from animals bred and raised in captivity in countries or geographic regions that have appropriate national health status, disease prevention, and control systems. In addition, the care and use of animals should be approved by a certified institutional animal care and use committee. Donor animals must have documented lineage, be obtained from closed herds or colonies, and be under health maintenance and monitoring programs. The facility for housing these animals should be USDA certified (large vertebrate animals) or Association for Assessment and Accreditation of Laboratory Animal Care International (AAALAC) certified (small vertebrate animals) and should meet the recommendations stated in the Guide for the Care and Use of Laboratory Animals (National Research Council, 1996), which can be obtained from the AAALAC. Such facility should be staffed with veterinarians and other trained personnel who will ensure animal health and disease prevention. The procedures employed in the facility should be documented and records should be kept. Health maintenance and monitoring programs are based on standard veterinary care for the species and include physical examinations, monitoring, laboratory diagnostic tests, and vaccinations. Use of a stepwise batch or all-in-all-out method of movement of source animal through the facility, rather than the continuous replacement movement, is recommended. It allows the decontamination of the facility prior to the introduction of the new set of animals, thereby reducing the chance of disease transmission. Feed components should be documented and should exclude, whenever possible, recycled or rendered materials that may have been associated with the transmission of prior-associated diseases.

To provide a high degree of assurance of product safety, screening of donors and of tissues derived from these donors should be performed at several stages throughout the process to rule out the presence of microbial agents. These control tests should utilize assays that are sufficiently sensitive and specific to detect bacteria, mycoplasma, fungi, or viruses of interest. Donor animals can be screened for certain diseases prior to donation of tissue by applying a variety of serological monitoring tests. Tissues can be subjected to a panel of tests including, but not limited to, the following:

1. test for sterility;
2. test for mycoplasma;
3. test for cultivable viruses in vitro;
4. test for unknown viruses by inoculation of various laboratory animals;
5. tests for xenotropic endogenous retroviruses and other animal retroviruses by in vitro cocultivation techniques, biochemical methods (for instance, to detect viral reverse transcriptase), and molecular biology assays (such as PCR assay for viral genomic sequence detection); and
6. direct detection or observation methods such as electron microscopy, detection of specific viral antigens by fluorescent antibody microscopy, or enzyme immunoassay methods.

Most of these tests are addressed under Analytical Methodologies or under [Biotechnology-Derived Articles](#) [1045](#) and [Viral Safety Evaluation of Biotechnology Products Derived](#)

from [Cell Lines of Human or Animal Origin](#) (1050). Post-tissue retrieval necropsies, sentinel animal programs, and archival storage of donor organs, tissues, blood, and other specimens are additional components of the overall program to ensure the safety of animal tissue for use in cellular therapeutic applications.

Most of the same aseptic procurement issues apply to animal tissue and to human tissue. Again, the tissue should be obtained under environmental conditions and controls that provide a high degree of assurance of aseptic recovery. Specifically designed procurement facilities, usually closely associated with the animal holding facility, are typically employed.

These facilities have specific attributes and design features that may not be available or applicable in the hospital operating-room setting. Such features include the following: (1) staging of various events, such as shaving, sedation, and operating-room preparation, in different rooms that are often separated with air locks for environmental control; (2) high-efficiency particulate air (HEPA) filtration; (3) adjacent but separate facilities for further tissue processing; and (4) dedicated areas for carcass removal. The issues regarding the training of personnel, bowel manipulation and puncture, and disinfection that are applicable to human tissues apply to the surgical procurement of tissue from animals as well (see [Human Tissue](#)).

#### Cell Isolation and Selection

##### general considerations

The general principles for processing human and animal tissues following aseptic procurement are independent of the tissue source. The manufacture of cell products may occur at a clinical site or at a central cell-processing facility. Sites involved in cell processing should ensure reproducibility and safety of the manufactured products through appropriate QC and QA programs.

Regardless of the location, processing should occur in a dedicated area physically separated from the site of procurement. To the greatest extent possible, the facility design and processing procedures should be consistent with those provided by the FDA's Guidelines on Sterile Drug Products Produced by Aseptic Processing (June 1987), or provided under [Pharmaceutical Compounding—Sterile Preparations](#) (797) for processes involving open manipulation. Generally, this requires that properly trained and outfitted processing staff handle blood or tissue samples in a critical zone supplied with class 100 HEPA-filtered air, which is provided by a biological safety cabinet located in a controlled clean room supplied with class 10,000 HEPA-filtered air. The facility and processing areas should be monitored for air quality in a manner that provides a high level of process asepsis. For guidance in this area, see [Microbiological Evaluation of Clean Rooms and Other Controlled Environments](#) (1116). The material should be packaged in sterile, leak-proof containers and transported from the procurement area to the processing area under controlled conditions that maintain cell viability. The fluid medium in which the specimens are bathed during transportation should be optimized to maintain cell and tissue viability. This transport medium can be supplemented with antibiotics. If so, the antibiotic levels in process buffers are decreased and eventually eliminated during subsequent processing steps, so that antibiotics are not present in the final cellular product. In the case of blood products or tissues containing substantial amounts of blood, the transport media or buffered electrolyte solution should contain an anticoagulant such as heparin or a citrate-based material.

##### isolation

Solid organs or tissues are usually dissected to expose a desired region. This material may be used as is for transplantation or it may be processed further. If multicellular organoids (for instance, islets of Langerhans) or single-cell suspensions are desired, the tissue may be subjected to mechanical or enzymatic disaggregation. Physical disaggregation may be accomplished through the use of instruments that impart high shear forces on the material (namely, to homogenize) or break the tissue into smaller pieces. Alternatively, the material can be pressed or passed through screens of defined mesh sizes.

Enzymatic digestion of the extracellular connective tissue, which holds cells together within the tissue, is another common method for dissociating solid tissue. Typically, the tissue is minced into small cubes, usually larger than 1 mm<sup>3</sup>, and incubated in a buffered solution containing a digestive enzyme. Alternatively, the intact organ is infused with a solution to rinse the blood from the tissue followed by the enzymatic solution that aids the digestion. Various enzymes are used to accomplish this. Examples include collagenase, trypsin, elastase, hyaluronidase, papain, and chymotrypsin. Enzymes with nuclease activity, such as deoxyribonuclease, may be added to digest nucleic acids released from damaged cells, preventing excessive cell clumping. At the end of the incubation process, the cell suspension may be subjected to a mild pumping action to further break up multicellular clusters into those of desired size or composition. Enzymatic and physical disaggregation methods are often combined to achieve the desired result.

Because cells isolated from blood and bone marrow products are inherently cell suspensions, mechanical manipulation is limited to plasma removal, which is accomplished by centrifugation and physical removal of clots that occurred during transport via 200-μm filtration.

##### selection

Cell suspensions at this stage may be transferred directly to culture vessels as described for Propagation under Cell Propagation and Differentiation, genetically manipulated as described under Introduction of Genetic Material into Cells, or formulated by various techniques as described under Formulation of Cell Therapy Products. Cell suspensions often consist of a mixture of cell types that may require further processing to isolate a cell population of interest or to decrease the level of an undesirable cell type such as potentially contaminating tumor cells. Various cell isolation and separation techniques exist that provide high yields of pure cell populations.

Each cell type typically possesses specific size and density; therefore, different cell types will sediment at different rates in a centrifugal field or at unit gravity. Cell populations can be selectively sedimented to yield pure fractions by varying the centrifugation forces and the duration of centrifugation. Separation can also be achieved by isopycnic centrifugation, where the cell suspension is centrifuged in a gradient medium that encompasses all of the densities of cells in the sample. In this procedure, the various cell populations sediment to an equilibrium position at the gradient density equal to the density of the cell population. Specifically designed continuous-flow elutriation centrifuges separate cell populations by subjecting a cell suspension to opposite centrifugal and fluid stream forces in a special chamber within the centrifuge rotor mechanism. Cell populations separate within the rotor on the basis of their various sizes and densities, and they are selectively eluted out of the rotor chamber by increasing the fluid stream force. Finally, methods that do not require centrifugation but instead involve the addition of high-density agents, such as hydroxyethyl starch, to the cell suspension will result in cell separation. The mixture is allowed to settle in a tube at unit gravity, resulting in the separation of different cell types based on buoyant density. Concentration and separation procedures such as these frequently result in cell loss due to clumping and aggregation.

Cell separation can also be achieved by applying techniques that take advantage of unique cytological or biochemical characteristics of different cell populations. Soybean agglutinin binds to and agglutinates cells that bear a particular carbohydrate moiety expressed on mature blood cells, but not stem cells, allowing for purification of the stem cells. Lymphocytes possess the CD2 antigen that acts as a receptor for sheep red blood cells. The lymphocytes form rosettes, which then can be separated via differential centrifugation.

Some applications take advantage of the ability of certain cell populations to adhere to the surface of specific solid substrates such as tissue culture plastic, collagen-coated materials, and natural and synthetic polymeric scaffolds. The specifically bound cell type is selectively recovered onto the surface and removed from the initial cell suspension. When placed under the appropriate culture conditions, these cells will multiply and eventually occupy the available surface or void volume of the substrate.

Monoclonal antibodies directed against specific cell surface antigens or receptors can be used for both positive and negative cell selection. For example, a monoclonal antibody-labeled cell population can be removed from the cell suspension immunomagnetically, after exposure to magnetic particles coated with antimonoclonal antibody. The magnetic particles and their bound cells are removed from the cell suspension magnetically. Cells are released from the complex following incubation with reagents, such as specific peptides, that dissociate the monoclonal antibody from the cell. Unlabeled cell suspensions can be poured over or incubated on surfaces such as plastic flasks or microspheres coated with monoclonal antibodies as a means of isolating particular cell populations. In addition, a fluorescence-activated cell sorter (FACS) can be used to separate different cell types by binding antibodies tagged with fluorescent markers to a particular cell type.

Various other techniques purify particular cell populations by destroying unwanted cells present in the mixture. For example, certain cell-bound monoclonal antibodies are able to fix and activate complement, which is added to the cell suspension, resulting in lysis of the cell. Some procedures use cytotoxic agents or mitotic inhibitors to selectively impede or kill unwanted cells in a cell product. These methods typically target an unwanted cell subpopulation with a high growth rate, such as tumor cells. Finally, an antibody can be conjugated to a toxic moiety, such as ricin, allowing delivery of the cytotoxic agent to the targeted cell population. Most of these procedures require several washing steps after the exposure of the cells to the cytotoxic agents to ensure the removal of the dead cells, cell fragments, and cytotoxic agents from the final cell product.

#### Cell Propagation and Differentiation

##### propagation

A key issue for cell therapy products is the ability to manufacture and deliver a therapeutically relevant dose of the required cell population to the patient. Depending on the application, the product may be a pure, homogeneous cell type or it may be a mixture of different functional cell types. Many target cell populations are present at low level or low purity in complex

primary source tissues. In such cases, production of a therapeutic dose may be achieved only by specific enrichment and propagation of the required cells.

Propagation of cells may occur in suspension culture (for example, T cells or hematopoietic stem and progenitor cells), adherent culture (for example, mesenchymal stem cells, embryonic stem cells, neuronal stem cells, or dermal fibroblasts), or a mixture of both (for example, bone marrow stroma expansion). Numerous devices of varying degrees of sophistication and automation exist for cell culture.

In the simplest iteration, cells can be propagated in tissue culture flasks (T flasks), roller bottles, on polymeric scaffolds, or nonrigid, gas-permeable bags inside regular incubator units that are controlled for temperature, humidity, and gas composition. Multilayered plastic cell factories, cell cubes, and multi-bag systems have been developed that enable expansion, harvesting, and formulation to be carried out in a closed system.

Traditional small-scale fermenter units can be used for expansion of cells in suspension culture. It is also possible to expand adherent cells in such units either by providing a surface for attachment (coated beads or disks) or by adapting the cells to propagate in suspension culture. Some culture systems are specifically designed for the propagation of cells for therapeutic applications. These systems tend to be closed systems that use disposable bioreactor cartridges, such as those made of hollow fiber or molded plastic, in automated processing units with direct control of parameters such as temperature, gas composition, and media perfusion rate. These units can provide a completely automated, closed system for expansion and harvesting. In some cases the automated software is set up for patient–donor tracking and will document culture conditions and manipulations for the entire processing run. These features are useful in the design and implementation of QC product-release testing programs and for the QA documentation of processing runs.

In the case of adherent culture, the cells are usually released from the surface upon which they have expanded. Methods of release include physical agitation, enzymatic cleavage with enzymes such as porcine or bovine trypsin, collagenase, or dextranase, chelation of metal ions (for example, with edetate disodium), and competitive inhibition of adhesion or matrix molecules. As described above, consideration must be given to the source, safety, toxicology, and residual testing for any reagent used to release adherent cells during manufacturing.

Some product-specific systems that do not require the release of adherent cells have been developed. In these systems, the cells are expanded upon a synthetic or natural matrix that is then applied topically (for example, in dermal repair products) or the cells are grown inside or outside of fibers for ex vivo perfusion (for example, hepatocytes in hollow-fiber devices to treat liver disease). In these applications, the matrix and device composition must be biocompatible and, in some cases, biodegradable.

In all of the above systems, standard cell culture parameters must be optimized for maximum process efficiency. Such parameters include composition of cellular source material, initial seeding density, media composition, rate of media exchange, temperature, gas composition, and rate of delivery. Depending on the nature of the product, the potential effect of process parameters on the potency and function of the target cells should be defined.

In closed bioreactor systems, it can be difficult to observe or sample cells so as to determine and control the rate of proliferation and thereby the point of harvest. Measurement of traditional fermentation parameters, such as rate of nutrient usage or production of metabolic products, can provide a surrogate method, amenable to validation, with which to evaluate the rate of proliferation and predict when to harvest the cell product. The relationship of such parameters to the viability, potency, and function of the cell product should be well defined. Postexpansion purification and enrichment of target cells by using methods such as those described above may be required.

#### differentiation

Some cell therapies require lineage or functional differentiation of the source cells. For example, hematopoietic stem cell expansion processes normally result in products containing a mixture of multipotent stem cells, lineage-committed progenitor cells, and lineage-differentiated cells. The composition of these products can be manipulated by using different combinations of growth factors and cytokines during the expansion process. The inverse is true for processes in which mature cells are de-differentiated to enable them to then be recommitted to a lineage pathway (for example, chondrocytes in cartilage repair).

Specific examples of ex vivo manipulation are the programming of professional antigen-presenting cells, such as dendritic cells and monocytes or macrophages, and the production of antigen-specific T cells to target various specific disease indications. In these applications, the manipulated cells may be engineered to target and attack a specific tumor or tumor cell type, to induce a specific antibody or other cellular response, or to potentially vaccinate a patient. The processes for production of such products can involve one or more exposures of the relevant cells to disease-specific synthetic immunogens (for example, peptides) or natural immunogens (for example, dead tumor cells, viruses, cell membrane fractions, or purified natural molecules) before, after, or during culture expansion. Alternatively, the target cells may be genetically engineered with a specific gene product, such as an HIV-specific receptor. In some applications, relevant cells are cocultured with tumor cells, other diseased cells, or cells producing a transducible or transfecatable gene construct to generate a specifically targeted product.

Again, prior to delivery, the manipulated target cells may require further purification and enrichment by applying the methods described throughout this section. In the case of certain T-cell products, the desired antigen-specific cells can be cloned and then further expanded to provide the therapeutic dose.

#### Introduction of Genetic Material into Cells

A common extension of cell therapy involves the introduction of genetic material, usually DNA, into cells to alter their pattern of gene expression. For the purpose of this section, it is assumed that the nucleic acid is DNA. Similar scenarios can be applied to RNA or a derivative of DNA, except that the stability and solubility of the particular nucleic acid may dictate modifications of certain steps. This process is often referred to as ex vivo gene therapy, because the cells are removed from the patient or donor and the genetic material is introduced while the cells are outside of the body. Genetically modified cells are then administered to the patient. The genetic material introduced can either cause the expression of new genes and products or cause the inhibition of the expression of already expressed genes and products. The latter represents a type of antisense therapy. The genetic material can be introduced by the same range of reagents that are involved with gene therapy: viral vectors, nucleic acids in a simple formulation (naked DNA), or nucleic acids formulated with agents, such as liposomes, that enhance their ability to penetrate the cell. Most of the steps and considerations discussed above also apply to the ex vivo introduction of genetic material into cells. However, the main goal of ex vivo therapy is to develop robust processes that will work with the majority of patient's or donor's cells. This takes considerably more effort than processes for cell lines.

The method of introduction of new genetic material into cells depends on the biology of the system and the desired stability of gene expression. If a simple retroviral vector such as Molony murine leukemia virus is used for transduction, the cells must be actively dividing because vector DNA is only integrated into the cellular DNA during replication. This usually leads to long-lasting expression of the desired gene product. Adenoviral vectors, naked DNA, or formulated DNA can be introduced into nondividing cells. However, gene expression will be transient, because the introduced DNA will usually be extrachromosomal.

The main challenge is to achieve efficient transduction or transfection, introducing sufficient DNA into the cell before the DNA degrades. In the case of transduction by retroviral vectors, vectors derived from simple retroviruses, cells are stimulated with reagents that cycle them into the S phase (replication) at the time the vector is applied. Most retroviral vectors are stable in cell culture for a period up to a few hours. Because diffusion is minimal, only a small fraction of viral particles will come into contact with cells over this period. The following techniques can be used to increase the number of viral particles that contact the cell in a given time period:

1. maximization of viral particle concentration and minimization of the media volume during the transduction step
2. multiple applications of the virus
3. centrifugation of virus particles onto the cells
4. placing of cells on a filter and slow pulling of viral media through the filter
5. addition of binding-enhancing polymers to the media.

note—Coculturing of the target cells with the viral producer cells is not recommended. This technique increases the chance of a recombinant event occurring and of the production of RCV. Furthermore, any product for which coculturing is used to transduce the human cells would be considered a xenotransplant if the producer cells were not human. The second cell type, whether human or not, may cause inflammation.

Each of the above techniques has its own set of issues that must be addressed in order to develop a robust process. In technique 1, reduction of the volume during transduction results in rapid exhaustion of the medium; therefore, supplemental medium should be added within a few hours. In technique 2, the cells may no longer be in the correct cell cycle phase during later applications or cells may have become refractory because of unproductive transformation during the prior application. Techniques 3 and 4 can work well on a very small scale, but the number of cells that can be transduced may be insufficient to obtain an efficacious dose. In technique 5, polymers may fail to provide a benefit because virus-binding may involve specific receptors whose surface density may prove to be the limiting factor.

similar issues and techniques can apply with other viruses or DNA preparations. The issue of slow diffusion is even more marked for the use of DNA preparations. Factors such as the cell type in which the viral vector was produced, the media used for vector production, and the purity of the vector can have a dramatic effect on the efficiency of transduction.

While certain methods may not require cells to be actively cycling, in practice, most processes will require that cells be capable of replication because of the following considerations:

1. Safety considerations may dictate that only cells that express the new DNA are returned to the patient, which requires that these cells be selected. As described below, the most common selection method utilizes an antibiotic-resistant gene that is co-introduced with the new genetic material.
2. Further propagation may be required to achieve the therapeutic dose of cells.
3. Economic, biological, or technical reasons may dictate that the DNA introduction step be carried out at a low cell number and that the desired cell population then be expanded to the required dose.

Therefore, conditions that enable the cell or maintain the cell's ability to proliferate must be developed in almost all cases. The biology of the cells, the available technology, and the process economics will determine whether cells are propagated before, after, or during the introduction of new genetic material. Most processes do in fact expand the population after the introduction of the new gene.

Whether cells that do not productively express the gene can be administered to patients depends on the biology of the application, the dose required versus the handling capability of the manufacturing system, and most importantly, the toxicity of the nonproductive cell population. Selection of the genetically modified cell population is commonly carried out using an antibiotic-resistance marker gene, such as neomycin, which is co-introduced into the cell with the new genetic material. For neomycin selection, cells in culture are treated with the antibiotic G418 at a concentration and for a period that have been shown to kill cells with nonproductive expression, while allowing the productively expressing cells to proliferate. In this manner it is presumed that cells that are resistant to the antibiotic will also express the DNA of interest. The expression should be tested as a lot-release requirement or verified in a series of mock runs. Because most antibiotics decrease cellular proliferation, optimization of the culture media composition may be necessary for efficient selection and propagation of the gene-modified cells.

Following the antibiotic selection step, a second phase of antibiotic-free cell propagation may be required in order to achieve the desired dose and to rinse residual G418 out of the system. The selected medium and the total time that the cells are in culture can be critical to maintaining the desired expression of the original differentiated functions. An additional issue associated with the use of selection markers is that they generally are nonhuman genes. The expression of these genes usually elicits an immune response.

Process development is often carried out with cells from healthy donors. Consideration should be given to the fact that for very sick patients, it can be difficult to obtain healthy cells that can be stimulated to undergo efficient, sustained replication.

#### Formulation of Cell Therapy Products

##### suspensions

Formulations for cell therapy products depend upon the desired length of storage and whether the cells are administered as a suspension or in combination with a matrix. Regardless of the route of administration, cells that will be administered as a suspension can be frozen or not frozen. The most common formulation for cells that are cryopreserved is a 5% to 10% solution of dimethyl sulfoxide (DMSO), with or without hydroxyethyl starch (generally 6%), and a plasma protein, such as 4% to 10% human serum albumin, in a balanced salt solution.

DMSO prevents dehydration by altering the increased concentration of nonpenetrating extracellular solutions during ice formation at the time of freezing. The high molecular weight polymeric hydroxyethyl solution protects the cells from dehydration as water is incorporated into the extracellular ice crystals. The use of protein often results in maximum recovery and viability of cells after thawing. Serum (5% to 90%) has been used in place of specific proteins. Some cryopreservation formulations are completely free of protein. If the solution contains a buffer, the pH of the buffer should not be affected by changes in temperature. The optimal concentration of cells for cryopreservation depends on the cell type, but it generally ranges from 106 to 107 cells per mL. The purity of the cell population can also affect recovery. For instance, granulocytes can be damaged by the cryopreservative and the cell viability can decrease. These effects are dependent upon the concentration of cryopreservative. Both effects subject the patient to an increased level of infusion-related toxicity, although this is related to the volume administered and the final concentration of the cryopreservative.

Formulations for cell suspensions stored without freezing generally contain cell culture media, often without any protein. Because cells continue to metabolize their media even at the reduced temperatures used for storage, the medium supplies the amino acids and other nutrients that help in maintaining cell viability.

##### products combined with biocompatible matrices

Many cell therapy products are administered in combination with a biocompatible matrix. For instance, wound healing or skin substitute products contain cells seeded on a matrix. The biochemical and physical structure of the matrix and the method for combining cells with the matrix are specific to the application. Some common examples include the following:

1. Cells loaded into a semipermeable membrane device—Usually the pore size of the membrane is large enough to allow the cell-secreted therapeutic factors to pass, but it is small enough to stop immunoglobulins and host cells from making contact with, destroying, or having an immune response to the therapeutic cells. The device can be a single hollow fiber or a semipermeable capsule with cells inside that secrete therapeutic compounds, or it can be part of a larger system of pumps and filters, such as hollow-fiber modules with hepatocytes for the treatment of liver disease.
2. Cells seeded onto a three-dimensional matrix and allowed to propagate and form a tissue-like structure—In the resulting product, the cells are oriented in a unique manner that is important for the intended use of the product (for example, skin substitutes). In some cases, mechanical force has been used for proper cell orientation.
3. Cells encapsulated in a gel or cross-linkable polymer solution—The resulting implantable structure can serve as a culture vessel, as a means to shield the cells from the host's immune system, or as a way to mold cells into a defined shape. Some of the polymers used include alginate, hyaluronic acid, collagen, chitin, or synthetic polymers.
4. Cells adhered to matrices of defined shape that are then implanted—Some examples include osteogenic precursor cells on matrices of demineralized cadaveric human bone, ceramic hydroxyapatite, ceramic hydroxyapatite-tricalcium phosphate, or biodegradable glass, which can be used in the repair of bone defects.

When manufacturing such products, the primary consideration is the sourcing of a quality matrix material. The matrix material should be biocompatible, should not interfere with cell function, and should not trigger an immune response in the patient. If it is intended that the cells proliferate after loading onto or into the matrix, the matrix and the supporting culture system must allow exchange of nutrients and waste products. Cells may form tissue-like structures under favorable conditions and for those applications where this is required. A thick, impermeable matrix will lead to forming regions of necrotic tissue. Many of these devices are designed so that they can be removed from the patient after a certain period of time.

In all cases where cells are combined with biocompatible matrices, the use of closed systems for the manufacture and the delivery of product is preferable. As cell therapy products of this type can be quite intricate, the manufacturing details for such products are outside the scope of this chapter.

#### MANUFACTURING OF GENE THERAPY PRODUCTS

##### Introduction

The principles applicable to the production of pharmaceutical or biological products are also relevant to the production of gene therapy vectors for therapeutic use in humans. The same CGMP requirements can be applied to determine product consistency, process validation, raw material qualification, and compliance of the manufacturing facilities. Manufacturers will face development issues such as scalability, yield, cost efficiency, and product stability.

Most gene therapy vectors have been produced only in relatively small batches necessary to meet the needs of early clinical trials in small numbers of patients. However, areas of rapid progress are large-scale production of vectors, vector purification, and suitable analytical techniques. This section focuses on issues involved with designing vectors for gene therapy and choosing a production technology; it does not focus on specific production technologies.

##### Design Considerations for Gene Vectors

##### types of vectors

A typical gene therapy vector is composed of (1) the vector backbone, viral or plasmid, (2) a promoter, (3) the therapeutic gene of interest, including introns, and (4) a polyadenylation signal. Murine and human retroviruses, adenoviruses, parvoviruses such as adeno-associated virus (AAV), herpes viruses, poxviruses, toga viruses, nonviral plasmid therapy systems, and synthetic antisense-oligonucleotide therapy systems are being developed for gene therapy applications. The properties of these vectors (see Table 5) differ greatly in terms of their capacity to deliver genes to cells. Some viral vectors preferentially target dividing cells while others are capable of transducing both dividing and nondividing cells. There are significant variations in transgene capacity, meaning that there are limitations on the size of the foreign DNA fragment that can be incorporated into the recombinant genome. The ideal gene therapy vector has often been described as one capable of efficient transduction, targeted delivery, and controlled gene expression. The level, timing, and duration of gene expression required will depend on the clinical indication. Low-level, long-term gene expression is thought to be required for some diseases including adenosine deaminase (ADA) deficiency or type A and type B hemophilia. High-level, short-term expression may be more appropriate for cancer when genes that induce apoptosis are used, or for cardiovascular disease where preventing hyperproliferation of smooth-muscle cells may impede restenosis of saphenous vein grafts.

Table 5. Types of Gene Vectors

FAMILY	RETROVIRIDAE	ADENOVIRIDAE	VIRAL PARVOVIRIDAE	HERPES-VIRIDAE	TOGAVIRIDAE	POXVIRIDAE	NONVIRAL
Example Species	Murine Leukemia Virus	HIV	Adenovirus	AAV	Herpes Simplex Virus	Sindbis	Poxvirus (Vaccinia)
Vector Characteristics							
Insert size limit	8 kb	8 kb	4.3 to 34 kb	4 to 5 kb	40 to 150 kb	5 kb	25 to 50 kb
Chromosome integration	Yes	Yes	No; episomal	Can be integrated or episomal	Can be integrated or episomal	No	Yes, but at very low frequency
Therapeutic protein expression	Stable	Stable	Stable or transient	Stable	Stable or transient	Transient	Transient
Vector localization	Nucleus	Nucleus	Nucleus	Nucleus	Nucleus	Cytoplasm	Nucleus
Types of cells transduced	Dividing only	Dividing and quiescent	Dividing and quiescent	Dividing and quiescent	Dividing and quiescent	Dividing and quiescent	Dividing and quiescent
Efficiency of gene transfer	High	High	High	High	High	High	Low
Expression of viral proteins	No	No	Yes, unless viral genes deleted	No	Yes	Yes	No
Other	Tropism can be altered by pseudotyping					Can be used as a plasmid therapy system	

#### vector design criteria

Vectors are designed and selected for disease states on the basis of the following criteria:

1. capacity to accommodate the DNA for the therapeutic gene and its transcription cassette
2. host–vector interactions, both cellular and humoral
3. capacity to target intended cells
4. control of therapeutic gene expression
5. vector replication status
6. capacity for integration into chromosomes of target cells.

Selection of the route of administration and manipulation of the total dose of vector are strategies that can be used to compensate for some features of specific vector systems. The design and selection of a vector system include the evaluation of the disease of interest.

Additionally, there are advantages and disadvantages for the manufacture of each of the different vector systems. Production consistency favors those systems with well-defined fermentation or culture systems, such as plasmid, retroviral, or adenoviral vectors, or chemically defined systems, such as synthetic antisense-oligonucleotide systems. For those viral vector systems that require helper functions (see below), a rationally engineered cell line can overcome the scalability and consistency limitations of cotransfections. Engineered cell lines can also eliminate the possibility of replication-competent recombinant virus appearing in viral culture. Use of a cell line that is adapted to suspension culture can affect scalability and cost efficiency.

#### targeting transduction

To be effective, a vector must first find and transduce its target cell. Viruses have a natural host range that is strongly influenced by the expression levels of specific cell-surface receptors in target tissues, the cell cycle status of the target cells, and the route of administration. Integrins are a class of cell-adhesion receptors known to interact with either the penton base or the fiber protein of adenoviruses. The Coxsackie and adenovirus receptor (CAR) is also known to interact with adenoviruses. However, the expression levels of integrins and of CAR vary according to tissue type, affecting the transduction efficiency of adenoviral vectors. Amphotropic retroviruses infect cells via a sodium-dependent phosphate transporter molecule that is expressed at a detectable level in every human cell type.

The host and tissue range can be modified or targeted by a variety of approaches. Retroviruses, and lentiviruses, in particular, encode an envelope protein that mediates virus binding and entry via a specific host-cell receptor. Envelope proteins from one retrovirus may be interchanged with a protein from another retrovirus or a protein, such as the vesicular stomatitis virus glycoprotein from an entirely different virus. This process is referred to as pseudotyping. Viral protein coats may be modified in several ways. By engineering the fiber and knob of adenovirus, it is possible to change the intrinsic integrin specificity. Similarly, viral coat proteins can be chemically modified for ligand-mediated receptor targeting. It is feasible to create ligand–plasmid fusion molecules for receptor-mediated targeting of nonviral vectors. Some lipid formulations for nonviral vectors incorporate antibody Fab fragments or ligands to target plasmid delivery.

With respect to cell cycling, adenoviruses easily infect both quiescent and rapidly dividing cells, while murine leukemia virus-based retroviral vectors are efficient only when transducing rapidly dividing cells. Lentiviral vectors can infect quiescent cells, including cells of neuronal origin. In general, nonviral vectors have lower transduction efficiencies than viral vectors.

Transduction efficiencies of nonviral vectors are strongly influenced by the formulation used and route of administration.

#### impact of humoral immune system

Regardless of the route of administration, the intended target cell, and the dose, the vector is likely to encounter some component of the immune system as it moves toward the target cell. For viral vectors, the humoral (antibody-based) immune system cannot readily distinguish between wild-type viral infections and recombinant viral vectors because the humoral response is directed against proteins contained in the viral coat or package. Protein-containing formulations of nonviral vectors can also elicit a humoral immune response. Either specific or cross-reacting humoral responses may pre-exist or they may be elicited during dosing, and the antibody response may vary in its capacity to diminish gene transduction in individual patients. It is possible to compensate for the neutralizing activity of the antibodies by increasing the vector dose or by altering the dosing interval to coincide with periods of low antibody titer. Because neutralizing capacity is frequently enhanced upon multiple dosing, effective dosing by repeated administration may be problematic. This issue is generally avoided by the use of nonviral systems. Alternatively, viral vectors can be engineered to evade the immune system. For adenoviral vectors, one approach involves increasing expression of specific viral genes that allow the virus to evade the host's humoral response.

#### impact of cellular immune responses

Once protein expression is under way, cellular immune responses can lead to a rapid removal of both viral and nonviral vector-transduced cells from the body and a decrease in therapeutic effectiveness. Although protein synthesis is not required for cellular immune responses to viral vector envelope proteins, *de novo* synthesis of viral genes can exacerbate host-cellular responses. To reduce potential cellular responses, viral vectors have been designed with specific backbone deletions to eliminate the expression of viral structural genes.

Examples of such vectors include the E1- and E4-deleted adenoviruses, the adenoviruses and herpesviruses in which all viral genes have been deleted (gutless) or are helper dependent, and the recombinant adeno-associated viral vectors. Certain plasmid sequences especially those with the CpG motif, can elicit a strong cellular immune response.

#### antigenicity of gene product

The therapeutic gene product may also be antigenic. When proteins that are retained in the target cell are used, cellular responses may eliminate the target cell. In some cases this is the desired therapeutic effect, particularly in the antigen-based immunotherapy for cancer or a viral disease. However, if sustained protein expression is required, the cellular immune response may decrease the effectiveness of the therapy or eliminate it entirely. The antigenicity of the therapeutic gene may reflect a variety of experimental conditions. If a gene such as the cystic fibrosis transmembrane conductance regulator (CFTR) is truncated to fit within a chosen vector, this modification may result in creation of a distinct antigen. By using the gene that encodes thymidine kinase derived from the herpes simplex virus (HSV), a foreign protein is introduced into a human subject and thus it can function as an antigen. Any patient with a monogenic deficiency disorder is at risk for lack of tolerance to the normal protein that is defective or absent in the disease state (for example, dystrophin in Duchenne muscular dystrophy).

#### complement inactivation

Retroviral vectors are also subject to another host-defense mechanism—the complement component of the immune system. Retroviral vectors are reported to be rapidly inactivated by complement in sera from primates, but not from lower mammals. In considering the replication cycle of retroviruses, it is known that glycosylation epitopes are derived from the host cell during the budding process. Because many retroviral vectors used in gene therapy are murine in origin and have been grown in mouse packaging cell lines, they will have envelopes containing mouse glycoproteins. When retroviral vectors are made in human cells, they are substantially more resistant to human complement. It is reasonable to assume that the mechanism of resistance involves incorporation of natural human cell-membrane complement control proteins that have been incorporated into the vector envelope during the budding stage of particle assembly.

#### vector localization within the target cell

Once the vector reaches the target cell, several factors can affect the level and duration of therapeutic gene expression, and these factors dictate the choice of an appropriate vector system for a specific clinical indication. The localization of the vector genome within the cell, the strength of the gene expression control elements, the stability of the message, and the stability of the translated protein will all affect the therapeutic impact. Alphavirus-based vectors, such as those derived from Sindbis or Semliki Forest virus, reside in the cytoplasm and typically exhibit a very high level of gene expression. Retroviral, adenoviral, and other viral vectors have advantages in gene delivery with their natural mechanisms for nuclear delivery of the therapeutic gene and reasonable levels of gene expression from viral or other promoters. Nonviral plasmid vectors are episomal and are often susceptible to DNA degradation when they are shunted into cell endosomes. However, some nonviral systems incorporate nuclear targeting signals as a means of increasing therapeutic gene-transcription efficiency.

#### tissue-specific promoters

Another means of controlling gene expression is to incorporate tissue-specific promoters to stimulate or to restrict expression of the therapeutic gene. Drug-responsive promoters are being used to control gene expression. Rapamycin, mifepristone, or the tetracycline on systems have been used to repress gene expression. This type of regulation may be required for certain proteins, such as erythropoietin, where constitutive expression may produce toxicity.

#### impact of replication status of vector

Replication status is another important consideration for vector design and selection. Viral vectors are most frequently constructed to be incompetent or replication-defective in order to limit uncontrolled vector spread and pathogenicity. However, when effective therapy requires infection of virtually all the target cells, replication can be engineered to be conditional when specific viral gene interactions are matched with intracellular pathway targets. When these targets are defective or missing, such as in cancer cells, the virus can replicate, but when the target cell is functioning normally, viral replication is repressed. One of the risks inherent in the use of conditionally replicating viral vectors is that the growth of the virus is not absolutely restricted to a single cell type, that is, the system may be leaky. As compensation, the susceptible target cells may be efficiently transduced at a dose that is significantly lower than that necessary for nontarget cells.

Nonviral vectors are normally designed as nonreplicating systems, but some groups are experimenting with replicating nonviral plasmids to increase gene expression levels given the low transduction efficiency of most nonviral systems and to increase the duration of gene expression. Additional preclinical studies are needed to establish the safety of these systems.

Artificial chromosomes have also been designed to take advantage of normal mechanisms for retaining gene expression in rapidly dividing target cells.

#### vector integration

The duration of gene expression is also a function of the stability of the vector genome. Retroviral vectors can stably integrate into the host-cell genome. Adenoviruses do not integrate because their DNA remains episomal. Recombinant adeno-associated virus (AAV) vectors integrate, but because the rep genes responsible for site-specific integration are normally excluded from the construct in order to increase the vector-packaging capacity, integration is not site-specific as it is for wild-type AAV. Nonviral plasmid DNA does not integrate efficiently. However, stable episomes have been observed in certain cell types, such as muscle cells. Site-specific integration can be a desirable feature for vectors intended to correct genetic disorders. Although it is not currently possible, the control of the site of integration is desirable in order to prevent insertional mutagenesis. Insertional mutagenesis has the potential to kill a cell, if a critically functioning gene is inactivated, or to predispose a cell to malignant transformation, if a tumor-suppressor gene is inactivated.

The success of any gene therapy product is dependent on the relationship between the vector-delivery system and the requirements of the disease application in terms of the site, level, and duration of therapeutic gene expression. It is unlikely that there will ever be a universal vector, and the challenge is in fitting the vector to the disease.

#### Manufacturing and Purification Strategies

##### vector construction

Viral and nonviral gene-transfer vectors are constructed by using standard molecular biology protocols. For viral vectors, the vector backbone consists of viral RNA or DNA sequences from which the regions encoding viral structural genes or the regions required for replication have been deleted. The deleted region of the vector is usually modified with specific restriction endonuclease sites used to allow insertion of the gene of interest. For nonviral vectors, the plasmid DNA backbone contains multiple restriction sites for cloning and the bacterial elements necessary for plasmid production. Vector backbones can accommodate single or multiple gene inserts depending on the maximum amount of sequence they can carry. The promoter that facilitates transcription of the gene insert can be a related viral promoter, such as murine leukemia virus long terminal repeat (MuLV LTR), or a heterologous promoter that is either tissue-specific, such as alpha crystalline promoter (of the eye), or constitutive, such as cytomegalovirus (CMV). For example, in a retroviral vector construct containing two gene inserts, transcription of one is regulated from the 5'-LTR-promoter sequence, while a second gene insert can be linked to an internal heterologous promoter from Simian virus 40 (SV40). The complementary DNA (cDNA) containing the therapeutic gene of interest, including its introns, is excised from its source by using restriction enzymes and is inserted at the multiple cloning site of the gene-transfer vector. The polyadenylation signal can be derived from multiple sources such as the SV40 virus or human growth hormone.

Characterization and testing of gene therapy vectors are described under Analytical Methodologies.

##### helper function systems

Recombinant viral vectors are most often modified to be replication-defective, a condition created by deletion or modification of the viral genes needed for replication and production of infectious virus. As a result, viral vectors require help to produce infectious vector particles. Helper functions are often provided by packaging cell lines to deliver the necessary viral element from a source outside of the gene of interest (in trans). Packaging cell lines should be designed to minimize the risk of production of RCV through recombination between the vector and the packaging elements.

Plasmids encoding the necessary elements are introduced into the packaging cell by standard methods such as calcium phosphate-mediated transfection or electroporation. If multiple trans-acting elements are needed, these elements are introduced on separate plasmids in order to increase the number of recombination events needed to form a wild-type viral genome, thus decreasing the frequency of the event. An additional approach to eliminate production of RCV is the elimination of common sequences between the packaging cell

plasmids and the gene therapy vector.

Stable packaging cell lines should be selected and clonal MCBs prepared. In retroviral vector production systems, typically the pro-viral form of the retroviral vector is stably incorporated into the packaging cell, resulting in what is referred to as the producer cell line. A stable, banked packaging cell-producer line will lead to consistency in production and control of adventitious agent contamination. Alternatively, the system can be transient, with the packaging plasmids transfected along with the gene therapy vector for each round of vector production. However, a transient transfection system is less efficient and limited in scalability.

Typical helper function systems are as follows:

1. Retroviral Vector Systems—The murine fibroblast cell line NIH 3T3 has been the basis for several packaging cell lines. The gag, pol, and env functions can be colocated on a single plasmid (PA317) or placed on individual plasmids (psi-CRIP). This increases the number of recombination events required to produce an RCV. The human embryonic kidney cell line 293 has been modified to be a packaging cell line for retroviruses, because use of a human cell line allows production of a retroviral vector that is not affected by the human complement system.
2. Adenoviral Vector Systems—HEK 293 cells are widely used to supply the E1 function necessary for efficient adenoviral replication that is deleted from first-generation adenoviral vectors. Other complementing cell lines, such as E1-modified A549 cells (human lung carcinoma) and the PER.C6 cell line (human embryonic retinoblast), have also been created to supply E1 or other missing functions. The latter contains the E1 region under the control of a phosphoglycerate kinase (PGK) promoter and has no flanking adenoviral sequences in order to eliminate production of replication-competent adenovirus (RCA).
3. AAV Vector Systems—These systems classically use adenovirus-infected human 293 cell lines transiently transfected with AAV helper plasmid containing the rep and cap genes, which are required for AAV replication and capsid formation, respectively, and which are deleted from the AAV vector. The HeLa cell line (from human uterine cervical carcinoma) has also been used as a transient production system. More recently, both of these cell lines have been used to establish stably transfected packaging cell lines that express rep and cap genes and in some cases express the adenoviral functions needed for AAV replication when rep and cap are present (E1a, E1b, E2a, E4, and VA RNA).
4. Gutless Adenoviruses—The manufacturing systems for gutless adenoviruses are similar to classical AAV vector manufacturing systems in that human 293 cells are transiently transfected with helper plasmid containing required adenoviral functions.

#### viral gene therapy vectors

Retrovirus and adenovirus have classically been produced on the laboratory scale by using traditional cultivation methods for anchorage- and serum-dependent cell lines, employing flasks, trays, and roller bottles. Initially, gene therapy vectors were produced by using these exact methods because large volumes of product were not required for early clinical studies. Cell bank systems are used as the source of cells and virus banks as the source of virus for clinical production. In most cases, supernatant is collected, clarified, and stored frozen in bags at  $-70^{\circ}\text{C}$ . In many early clinical trials unpurified supernatant has been used for ex vivo gene transfer.

More recently, larger-scale upstream production methods have been reported including suspension, bioreactor, and fixed-bed or microcarrier culture methods. Some groups have reported adapting their process cells to serum-free culture conditions. Cells are harvested and lysed or supernatant collected. The harvest is clarified and purified to remove host-cell debris, host-cell DNA, and other process-derived contaminants.

Traditionally, viruses are purified by gradient ultracentrifugation, but this is time-consuming and unsuitable for larger-scale production purposes. The selection of downstream process steps and their sequence is determined by the nature of the virus itself and the upstream process used for manufacturing the virus. As processes are being developed for the manufacture of gene therapy vectors, many different purification steps have been reported. These include ion-exchange and sulfonated-cellulose chromatography, zinc ion affinity chromatography, size-exclusion chromatography, and DNase or other nuclease treatments. AAV production and lentiviral production are complicated by a need for transient transfection or cotransfection of plasmid or helper virus. These processes have so far required anchorage-dependent cell lines that are difficult to scale up. The development of stably transfected cell lines would allow large-scale production.

#### plasmid vectors

Plasmids are double-stranded, circular DNA molecules that exist in bacteria as extrachromosomal, self-replicating molecules. They have been modified to serve as cloning systems, to contain multiple restriction endonuclease recognition sites for insertion of the cloned transgene, and to contain selectable genetic markers for identification of cells that carry the recombinant vector. Plasmid-based nonviral vectors are frequently used as gene delivery systems for both *in vivo* and *ex vivo* gene therapies. They are in the form of naked DNA or complexed with lipids or other agents that facilitate transfer across the cell membrane and delivery to the cell nucleus without degradation. An advantage of a plasmid-vector system is the efficient production of large quantities of the vector that is easily characterized and involves no risk of contamination with the RCV.

Nonviral vectors are typically produced by using an *Escherichia coli* bacterial system. Plasmids are transfected into *Escherichia coli*, and an appropriate single bacterial colony is selected and expanded to create an MCB. After reselection of a colony from a bacterial plate inoculated from the MCB, plasmid DNA is isolated from cultures that can range in size from 1 L on a laboratory scale to hundreds of L in bacterial fermenters. Plasmid DNA can be purified by several methods including affinity or ion-exchange chromatography and cesium chloride–ethidium bromide density gradients. Cesium chloride–ethidium bromide density gradients are not recommended for production of clinical-grade material.

#### oligonucleotide vectors

Antisense oligonucleotides are manufactured by synthetic chemistry procedures. Currently, the method of choice is solid-phase phosphoramidite chemistry. Synthesis is linear, rather than convergent, and a high level of efficiency must be maintained at each synthesis step. This is accomplished by using molar excesses of highly pure raw materials to drive the reaction kinetics towards completion. Synthetic oligonucleotide manufacturing may require metric-ton quantities of nucleoside phosphoramidites and other compounds such as activator and sulfur-transfer reagents for commercial-scale manufacturing. An issue for oligonucleotide manufacturing is that during the preparation of raw materials and the synthesis of oligonucleotides, precaution must be taken regarding moisture, because moisture is detrimental to both yield and purity. Purification of the single-strand oligonucleotide product requires removal of residual solvents and synthetic strand by-products. Nevertheless, current oligonucleotide-manufacturing technology is readily scalable and cost-efficient, and it results in products with purity levels similar to those of classical small-molecule pharmaceuticals.

#### formulation of gene therapy products

Final formulations for vector products are still in early development. So far, mannitol, sucrose, lipids, polymers, and serum albumin have been utilized as stabilizers. Aseptic filling of large numbers of vials, using classical manufacturing processes, may be problematic. For example, some viral vectors are thermally sensitive and storage at ultra-low temperatures is often required. Progress is being made in both viral and nonviral vector lyophilization and in the use of stabilizers for liquid formulations.

### ON-SITE PREPARATION AND ADMINISTRATION

#### General Considerations

One or more product modifications or preparative steps may be required prior to administration of the cell or gene therapy product to the patient. These modifications or steps are frequently performed close to the time of administration; and, therefore, they are performed under conditions not under control of the original manufacturing facility. The nature of these modifications is largely dictated by characteristics of the product in relationship to the particular application. These include thawing, washing, or filtration to remove unwanted cells or substances accumulated during storage, transfer to an infusible solution, or compounding with a vehicle or structural material. In addition, patient considerations, such as the need to dose the product according to patient weight or blood volume, may influence these steps.

All product modifications performed between the time of initial product manufacture and final administration to the patient should be viewed as a part of the overall manufacturing process. The practical implications of this concept are that the process controls must be established for all product storage intervals, transport steps, and modifications, starting with a clear definition of critical control points. Operational requirements for performing any of these steps after initial product manufacture include defined physical space with appropriate environmental controls, trained personnel, detailed standard operating procedures, and a comprehensive quality program.

The unique and irreplaceable nature of many cell and gene therapy products, many of which have originated from an autologous or a selected allogeneic tissue source, creates special considerations for product manufacture, release, and administration. It is critical to both anticipate the need for and to establish policies and procedures to guide product modification or administration steps in cases where predefined release criteria cannot be met. These procedures should include a mechanism to obtain medical consultation to assess risk and benefit

considerations for the patient and to provide complete documentation of any decision to modify predefined product specifications.

#### On-Site Preparation product manipulations

Prior to administration, on-site preparation of the cell or gene therapy product may involve one or more manipulations. These manipulations include the following:

1. Change in Final Container—The manufactured product may have been stored or transported in one container but may require transfer to a different container for administration.
2. Change in Physical State or Temperature—A product may require thawing from the frozen state or warming from the refrigerated state.
3. Change in Solution or Suspension—A product may have to be dissolved, diluted, or suspended in a liquid.
4. Addition to Biocompatible Structural Material—A cell or gene therapy product may need to be combined with living, natural, or synthetic structural tissue or matrix. Examples of matrix material include hollow fibers, fibrous sheets, gels, plugs, capsules, sponges, or granules.
5. Admixture or Compounding with Other Nonstructural Materials—A product may require mixing or compounding with drugs, cytokines, biologics, or other nonstructural materials.
6. Filtration or Washing—Unwanted materials in the manufactured product, such as particulates, cellular debris, metabolites, or compounds remaining from previous manipulations may require washing or filtration steps.
7. Sampling—Sampling of the final product immediately prior to administration may be required for certain clinical protocols.

#### facility requirements

Facility requirements for performing on-site preparative steps or administration of cell and gene therapy products depend on the nature of the products, their applications, and the manipulations required. The most important determinant of facility features is the level of risk for microbial contamination associated with each step. Definition of low-risk and high-risk conditions can be made according to a framework similar to that defined for Low-Risk Level CSPs and High-Risk Level CSPs in the CSP Microbial Contamination Risk Levels section under [Pharmaceutical Compounding—Sterile Preparations \(797\)](#).

#### release of final product

Cell and gene therapy products that undergo on-site preparative steps or manipulations must be subjected to appropriate checks or tests to ensure that all quality specifications are met prior to release for patient administration. The nature and extent of manipulations will determine whether release requirements or critical specifications must be added to those required immediately after initial manufacture. Pre-release requirements usually include the following:

1. physical inspection of the product, which typically includes measures to ensure appropriate product appearance with regard to color, turbidity, particulates or foreign matter, container integrity; product temperature; and accuracy and convenience of labeling;
2. review of process records; and
3. for patient-specific products, clerical checking of product labeling or records related to identity of the intended recipient.

In addition, products considered to be high-risk products according to the description under [Pharmaceutical Compounding—Sterile Preparations \(797\)](#) should undergo additional product testing. For all high-risk products, quality assays for the identity, potency, and purity of the active ingredients should be defined and performed. For high-risk products in Category II, sterility and endotoxin testing should be performed.

#### Administration to Patients

##### pre-administration requirements

Depending on the specific cell or gene therapy application, steps may need to be taken by trained patient-care staff to prepare the patient for product administration. These steps are aimed at ensuring that the product will provide the intended therapeutic outcome and at minimizing the risk of adverse effects.

In cases where autologous, selected allogeneic, or xenogeneic tissue is the source of the cell or gene therapy product, determination of patient suitability for the therapy, including the evaluation of histocompatibility between the donor and the recipient, typically occurs prior to the product preparation. However, because of the possibility of changes in clinical status of the patient after the time of tissue collection, such as fever, infection, recurrence or spread of tumors, or organ dysfunction, a thorough re-evaluation of the patient's general condition and suitability for therapy must be performed in close proximity to product administration. This evaluation usually includes a patient history, physical examination, and laboratory studies such as blood counts and chemistries. In addition, baseline physical or functional measurements, laboratory tests, or imaging studies relevant to the specific application may be obtained. Examples include pulmonary function tests for a therapy aimed at improving lung function, measurement of blood levels of an enzyme that is the gene product in a gene therapy application, and nuclear imaging of organs prior to anticancer therapies.

A variety of patient interventions related to route of product administration may be required before product administration. For cellular therapies requiring intravenous administration, patients with poor peripheral venous access may require placement of a central venous catheter. In applications where cells or matrices combined with cells are implanted into the patient, the site of implantation may require preparation in the operating room. This may involve surgically opening the site, removing the degenerated or damaged tissue, trimming of the adjacent tissue to accommodate the implant, and excising the tissue from a second site to be used as an anchor or support for the implant. For instance, in the case of cell products for wound healing, it is critical that the site for grafting be free from infection and that it demonstrates a well-prepared wound bed. In cells intended to repair cartilage defects, the site of damage needs to be prepared so that the cells can be applied to a watertight compartment. For applications involving direct administration of the product into an organ system (for example, bronchioalveolar system) or vascular network (for example, coronary arteries), the patient may require endoscopic or surgical access to these sites.

In all cases, the need for adequate anesthesia and premedication must be carefully evaluated in conjunction with these steps prior to product administration. For example, if it is anticipated that DMSO will remain in a thawed, cryopreserved cellular product, the patient is given an antihistamine prior to administration of the cells to block adverse effects associated with histamine release induced by the DMSO. Pre-administration patient evaluation must also include assessment of concurrent therapies that may interact with the cell or gene therapy product to modify its effects. Some therapies may be considered adjunctive to the cell or gene therapy, such as cytokines that promote proliferation or differentiation of the infused or implanted tissue. Other commonly used drugs such as antibiotics, antineoplastics, anticoagulants, and anti-inflammatory agents must be evaluated for possible effects on the efficacy of the cell or gene therapy product.

#### patient treatment

Some cell or gene therapy products are patient-specific, in that they are manufactured from a selected tissue source, such as autologous, selected allogeneic, or xenogeneic tissue. Certain patient-specific products have a defined potential for benefit or adverse immunoreactivity. Systems must be in place to prevent administration of such a product to the wrong patient. Recommended systems include procedures similar to those used for administration of human blood products, with special attention given to the correct identification of the patient and patient-specific product by at least two people immediately prior to administration.

Cell and gene therapy products can be administered by a variety of routes. These include the intravenous route, the parenteral routes (subcutaneous, intramuscular, and intra-arterial), and the respiratory or gastrointestinal tract route. Other possibilities include direct application of cell or gene therapy products into regional vasculature, organs, tissues, or body cavities by means of needles or catheters or following surgical exposure of the tissue. While parenteral administration can be accomplished in routine outpatient or inpatient facilities, the other means of administration may require specialized facilities, such as an aseptic operating theater or endoscopic suite. In all cases, standard operating procedures and a quality program must be in place to ensure that the product is administered in the intended manner.

#### postadministration monitoring of patient

There should be written policies and procedures for monitoring patient outcomes and managing reports of adverse events. Patient-outcome assessment should include indicators that are likely to detect errors or problems related to the entire manufacturing process, with special attention given to manipulations, storage, or transportation after the initial manufacture of the product. Management of adverse reactions should include procedures for ensuring prompt medical evaluation and treatment of patients with suspected adverse effects and a

stem for reporting and evaluating adverse effects that may point to a potential defect in the administered product. Reporting procedures include providing details required for federal, state, or USP adverse-event reporting programs.

Follow-up and monitoring procedures should be implemented for patients who have received gene therapy vectors or ex vivo gene therapies. To the extent that it is relevant and that it can be assessed, vector or modified cell biodistribution and persistence in vivo should be monitored. With direct administration of vectors, localization to the germ line may be an issue.

Although preclinical studies can be used to address this issue, useful information may be gained through patient monitoring. In the case where a retroviral vector has been administered, patients should be monitored for replication-competent retrovirus (RCR) according to the FDA's Draft Guidance for Industry: Supplemental Guidance on Testing for Replication Competent Retrovirus in Retroviral Vector Based Gene Therapy Products and During Follow-Up of Patients in Clinical Trials Using Retroviral Vectors (October 2000). This involves active monitoring during the first year and archiving of patient samples thereafter if RCR is not detected initially.

Database systems to collate and track patient-monitoring results are essential to management of this information. National registries or publication of data should be considered for establishing the collective safety of gene therapy.

#### ANALYTICAL METHODOLOGIES

##### General Considerations

The complexity and scope of cell and gene therapy products is reflected in the wide range of analytical methods that are used to assess product quality. Approved cell and gene therapy products must comply with applicable sections of 21 CFR 211 and 21 CFR 610 to ensure their identity, dose, potency, purity, and safety. Specific guidance for the identification, development, and validation of analytical methodologies to support cell and virus bank characterization, final-product release, and stability studies is currently provided in the Center for Biologics Evaluation and Research (CBER) Points to Consider for Human and Somatic Cell and Gene Therapy (April 1998); under [Validation of Compendial Procedures \(1225\)](#); and in the ICH guidelines entitled "Q2A Validation of Analytical Procedures", "Q2B Validation of Analytical Procedures: Methodology"; and "Q6B Specification, Tests and Procedures for Biotechnological/Biological Products". Most product-specific analytical methods for cell and gene therapy products have not been standardized. Even well-defined tests such as those described under [Sterility Tests \(71\)](#) may not be directly applicable to certain cell and gene therapy products. For some cell and gene therapy products, large quantities of clinical material may not be available during early clinical development. Some required tests (e.g., sterility) may have to be modified. Consultation with the regulatory authorities is advised.

[Table 6](#) provides an overview of the product-specific testing parameters for the biological component and general methods or approaches being used to satisfy the testing requirements for cell therapy products and for nonviral, viral, and antisense-oligonucleotide gene therapy products. The analysis of cell and gene therapy products relies heavily on biological assays but it also utilizes methodologies developed for biotechnology-derived products (see [Biotechnology-Derived Articles \(1045\)](#)). Antisense-oligonucleotide products are regulated by the FDA Center for Drug Evaluation and Research (CDER) and rely heavily on physicochemical methods. The intent of this section is to outline the types of methods and their specific applications with regard to product characterization, stability, and release testing. Process validation may alleviate the need for certain specific lot-release tests. Development of appropriate reference materials and standards for cell therapy and viral and nonviral gene therapy products should be a part of product development. Reference materials should be fully characterized in order to provide continuity between standards over time. In the case of cellular products the reference material may be a surrogate tissue or simulated product.

Table 6. Analytical Tests for Cell and Gene Therapy Biological Products

		Gene Therapy Products	
Test	Cell Therapy Products	Viral	Nonviral and Antisense-Oligonucleotide
Identity of biological substance	Surface marker determination	Restriction enzyme map	Restriction enzyme map
	Species	PCR	PCR
	Morphology	Immunoassay for expressed gene	Immunoassay for expressed gene
	Bioassay	Sequencing	Sequencing
	Biochemical marker		
Dose	Viable cell number	Particle number	Plasmid-DNA weight
	Enumeration of specific cell population	Transducing units (DNA hybridization assay)	Formulated-complex weight HPLC or capillary electrophoresis assay using authenticated reference standard
	Total DNA	Total protein	
	Total protein	HPLC assay using authenticated reference standard	
Potency	Viable cell number (cells intended for structural repair)	Function of expressed gene (induction of secondary effect and other bioassays)	Function of expressed gene (induction of secondary effect and other bioassays)
	Bioassays: Colony-formation assay Function of expressed gene Induction of secondary effect (e.g., human leukocyte antigen (HLA) induction, secretion of cytokines, and up-regulation of surface marker)		
Purity	Percentage of viable cells	Residual host-cell DNA	Percentage of specific physical form (e.g., percentage supercoiled)
	Percentage of transduced cells	Process contaminants (e.g., serum and cesium chloride)	Residual host-cell DNA
	Percentage of cells with specific surface marker	Residual helper virus	Residual RNA
	Process contaminants (e.g., serum)	Optical density ratio	Residual host-cell proteins
		Residual host-cell proteins	Residual solvents
		Viral protein profile (HPLC assay for defective or immature particles)	Optical density ratio
		Residual RNA	Process contaminants (e.g., cesium chloride and synthetic oligonucleotide by-products)
Safety	Mycoplasma	General safety	
	Sterility	Mycoplasma	Mycoplasma
	Pyrogen and endotoxins	Sterility	Sterility
	Adventitious viruses	Pyrogen and endotoxins	Pyrogen and endotoxins
	Residual virus (for transfected cells)	Adventitious viruses	

Replication-competent vector virus (transfected cells)

RCV

Cell therapy products may require a rapid-release approach if they have a limited shelf life. The rapid-release approach is not usually applied to viral and nonviral gene therapy products because these products are sufficiently stable for completion of testing prior to release. Some formulated nonviral gene therapy products also have limited shelf lives. In such cases, the individual components are tested prior to release and the formulated complex is not tested. The formation and stability of the formulated nonviral gene therapy complex is established through validation studies during product development.

As specified in the CFR, product samples must be retained after product-release testing is completed. Additional samples may need to be retained if rapid-release strategies are employed, so that the product quality can be reassessed by alternative or traditional test methodologies if necessary.

#### New Methodologies and Compendial Perspective

Although the application of compendial methods is encouraged, there are many instances where the analytical method that best addresses the issue is a new method not found among the compendial methods. USP encourages the development of appropriate methods and submission of these methods, once validated, to the USP for addition to the compendia.

One such new methodology is the PCR-based assay. PCR-based assays are utilized in a variety of applications for both cell and gene therapy products. PCR assays can be a viable substitute for long-term bioassays and should be considered when a rapid-release strategy is used. Other applications include the use of PCR-based assays to assess adventitious viral agents in product or in cell and virus banks. PCR might also be used in an identity test of a gene therapy product. In all cases, validation of the new method and assay equipment and qualification of analytical personnel are required.

PCR assays are based on amplification of specific target DNA by using PCR technology. Traditionally, a pair of DNA oligonucleotide primers is used in combination with nucleotides and the Taq polymerase to increase the amount of a specific-size oligomer in a series of alternating cycles of permissive and nonpermissive polymerase temperature conditions. The reaction mix is resolved by gel electrophoresis and visualized by staining with ethidium bromide in order to detect the amplified target (amplicon). RT-PCR involves the use of a reverse transcriptase to create cDNA from RNA prior to performing the PCR reaction, so that the RNA can be detected. PCR and RT-PCR methods can be used qualitatively (positive or negative readout) or quantitatively.

Currently there are two common approaches to quantitation using PCR: (1) competitive PCR that involves use of a spiked mimic and (2) real-time or kinetic PCR that is based on the 5' nuclease activity of the Taq polymerase. In competitive PCR, quantitation is based on the ratio of the amplified mimic to the amplified target. In real-time PCR, the degradation of a dual-labeled, fluorescent, target-specific oligonucleotide probe is monitored in real time, as PCR amplification is occurring. The probe is labeled with a reporter fluorescent dye at the 5' end and a quencher fluorescent dye at the 3' end. When the probe is intact, the fluorescence emission of the reporter is quenched as a result of the physical proximity of the two dyes. The probe sequence is selected so that it hybridizes to the target between the two primer sites. During the extension phase of the PCR cycle, the probe is cleaved by the 5' nuclease activity of the Taq polymerase, while the reporter dye signal is increased by the release of reporter dye from the probe. Additional reporter dye molecules are cleaved during each cycle, resulting in an increase in the fluorescence intensity of the reporter dye proportional to the amount of amplicon produced. The resulting relative increase in reporter fluorescent dye emission is detected in real time during PCR amplification and it allows the threshold cycle number to be related to the target copy number. The threshold cycle number is defined as the PCR cycle number where the increase in reporter fluorescence is detected above the background fluorescence in the assay system. A greater quantity of input DNA or messenger RNA (mRNA) results in a lower threshold cycle, as a result of requiring fewer PCR cycles for reporter fluorescence-emission intensity to reach the threshold. Typically, assays can be designed to detect 1 to 10 copies of the target per reaction.

Like all analytical methods used to release product, PCR assays must be validated. Validation should include the rationale for the selection of primer and probe sequences and a demonstration of the specificity and efficiency of the primers and, for real-time quantitative PCR assays, of the probe. Because primers and probes are the main components of a nucleic acid-based detection system, the performance of the assay is highly dependent on the quality of these reagents. Specificity is generally demonstrated by assessing the resulting PCR product by gel electrophoresis to show that the amplicon is the expected size. For quantitative assays, the design and nature of the quantitation standards must also be addressed.

Assay validation must also address linearity, accuracy, ruggedness, and reproducibility with regard to both the assay itself and the sample preparation, that is, extraction of the sample DNA for PCR or of the sample RNA for RT-PCR. Validation should include a demonstration of the specific limit of detection in the sample type employed, because some sample types contain inhibitors of PCR. Validation should also address the reproducibility of the sampling scheme and the efficiency of nucleic acid extraction and purification procedures to produce the starting material (DNA or RNA). Well-designed spiking studies where samples are spiked both prior to and after extraction can address these issues.

PCR assays are occasionally subject to false-positive results because of the contamination of equipment or samples during handling in preparation for the assay. The most abundant source of contaminating target nucleic acid is the previously generated amplicon. However, the PCR reaction can be modified so that the resultant amplicon is sensitive to uracil-N-glycosylase digestion and can therefore be eliminated. In addition, isolation of sample preparation areas from other phases of the assay and the use of dedicated equipment for each assay phase are generally necessary to prevent amplicon contamination of test samples and, hence, false-positive signals. Assay protocols that include appropriate controls, such as nontarget sequence and nucleic acid-free controls, can aid in determining the source and point of contamination if it occurs. Validation should address the procedures implemented to prevent contamination.

#### Sampling Issues

Sampling for lot-release testing should be based on the potential distribution for the parameter tested. See Stability-Protocol Development under Stability for additional considerations. Samples from each lot need to be retained in case there is a safety or quality issue with the lot. Even if the product has a very short shelf life, these retained samples can be used to detect impurities and other substances. The need for proper design of the sampling scheme is highlighted in safety testing for adventitious agents for cell or viral gene therapy products or in assessment of RCV for viral gene therapy products. In such cases, process validation will assist in determining the appropriate statistically based sampling design.

#### Safety general considerations

Safety testing for cell and gene therapy products focuses on three issues: (1) preventing the unwitting use of contaminated cells, tissues, or gene therapy agents with the potential for transmitting infectious diseases, (2) preventing the use of improperly handled or processed, and consequently contaminated, products, and (3) ensuring safety when cellular and gene therapies are adapted for use other than in their normal functions or setting.

The primary means of assessing safety are the performance of biological assays to measure adventitious agents directly. Molecular biology-based assays that measure adventitious agent DNA or RNA are also used.

#### cell therapy products

Direct transmission of infectious disease is a major concern for cell therapy products. The degree of risk is dependent upon various factors such as whether the cells or tissues are to be used in a person different from the one they were obtained from; whether they are banked, shipped, or processed in a facility that handles cells and tissues from multiple donors; and how extensively they are processed. Improper handling can alter the integrity and function of cell therapy products by introducing microorganisms or by contaminating the therapeutic cell products with other donor or patient cells during collection, processing, or storage.

In addition to transmittable-disease screening and testing of allogeneic donors of all viable and nonviable tissues intended for use as cell therapy products, appropriate labeling and tracking are required. These requirements are not only based on the potential risk of disease transmission from donor to recipient but also on the following: (1) the unusual, but documented, possibility of product-to-product transmission (for example, viral contamination may occur among disrupted bags in the liquid phase of a liquid nitrogen freezer) or (2) the possibility of erroneous administration of a product to the wrong recipient. Specific donor screening and testing requirements for allogeneic cell products are based on those currently required for human blood products. These include (1) specific donor testing for HIV Type 1, HIV Type 2, hepatitis B, hepatitis C, and syphilis and (2) medical history screening for high risk for HIV, hepatitis B, Creutzfeldt-Jakob disease, and tuberculosis. Some of these tests and screening measures are also recommended, but not required, for autologous tissues.

The risk of cross-species infectivity during xenotransplantation is still unknown. Assessing the risk of infection from a new transmissible agent is difficult. In vitro coculture assays involving sensitive human indicator cell lines for the donor species should be developed. In particular, assay of endogenous retrovirus (ERV) present in the xenogeneic cell or tissue is required. In the case of porcine cells and tissues, both PCR and RT-PCR assays for porcine endogenous retrovirus (PERV) have been described and are applied to donor cells and

issues. These tests are also being used for patient monitoring. Assays for PERV antibody have also been developed for patient monitoring. Published studies indicate that the risk of PERV transmission to patients may be low.

Often the shelf life of cell therapy products is shorter than the time required to test for sterility and adventitious agents using traditional cell-based methods. However, as already discussed, development of validated rapid PCR-based methods allows both assessment and timely release. Presence of mycoplasma and a range of specific adventitious viruses and bacteria can be tested by using PCR or DNA- or RNA-hybridization dot blot analysis. Fourteen-day sterility testing is not always a viable alternative for final release of cell therapy products; in such cases, automated methods that rely on colorimetric detection or on continuous monitoring may be acceptable if they are validated. Facility and process validation are necessary adjuncts to ensure safety with regard to sterility and mycoplasma, particularly when rapid-release strategies are employed.

Additional testing for safety may be required when cell therapy products are used in the patient for a purpose other than that which the cells or tissue fulfills in its native state or when placed in a location of the body where such structural function does not normally occur. Testing should be designed to predict product behavior under these settings and should be designed based on the context of use. For example, in the case of a cell therapy product for cancer patients, where the cells are activated by culture on a feeder layer of cells during processing, it may be necessary to test the product cells for the presence of feeder cells. Residual feeder cells in the final product may cause an inflammatory response. In addition, products using non-human feeder cells are considered xenogeneic products. Cell therapies are exempted from general safety testing.

If the cells were modified by a viral gene vector during manufacturing, presence of RCV must be tested. Typically, RCV testing (see *Viral Gene Therapy Products under Safety*) is limited when rapid release is required by shelf life. Again, molecular biology-based methods such as PCR can be used in rapid screening situations. In such cases, during product development, testing that employs cell-based assays (for example, detection of cytopathic effect on indicator cell lines) is performed after release to validate the molecular biology-based test result.

#### viral gene therapy products

One of the primary safety concerns associated with viral vectors used for gene therapy is RCV. Regardless of the virus, these concerns are based on the potential lack of predictability for the pathogenicity of a contaminating virus for a specific route of administration, particularly if it is not the normal route of infection or if humans are not a natural host for the virus.

The pathogenesis of a wild-type adenovirus infection is known but may not be predictive for the routes of administration employed with recombinant adenoviral vectors. For adenoviral vectors, a limit of one RCA per dose is currently considered acceptable; other limits have been established for dose levels greater than  $1 \times 10^9$  particles, specific indications, and routes of administration based on preclinical safety studies and patient-monitoring studies during clinical development. Limits as high as several thousand RCAs per dose have been reported. Typically, RCA levels are determined by using a cell-based assay that allows amplification of the RCA while preventing replication of the product. The cell line recommended for amplification and detection of RCA is the A549 cell line. However, some recombinant adenoviral vectors express therapeutic genes that interfere with analysis on A549 cells. In such cases, a bioassay utilizing two cell lines is used, with the first cell line chosen on the basis of resistance to the effects of expression of the therapeutic gene of interest and with subsequent passage of cell lysate onto A549 cells for amplification and detection of the RCA. RCA is most often detected by visual observation of the cytopathic effect but it may also be detected in the A549 cell culture by using immuno- or PCR-based methods. Quantitation of the RCA level is based on the quantity of sample tested and the detection limit of the assay. Typically, RCA bioassays are validated as being able to detect 1 plaque-forming unit or infectious unit of RCA in the test sample over a wide range of test-sample sizes. Test-sample sizes can range from  $1 \times 10^8$  to  $1 \times 10^{12}$  particles but they are typically based on clinical-dose size. To verify detection limits, spike controls should be included as part of the test, even with validated assays. For recombinant adenoviruses produced using 293 cells, RCA detection by PCR methods can be confounded by detection of residual 293 host-cell DNA (detection of the E1 region). PCR assays, however, can be designed to specifically quantitate host cell DNA contamination and can be made specific to particular forms of slow-growing RCA. Quantitative PCR assays can be used in conjunction with a cell-based method for precise quantitation of RCA levels. When a tested sample is found to be positive, the identity of the RCA is usually confirmed by conducting PCR analysis. This rules out the possibility that contamination of the assay by exogenous wild-type adenovirus or other adventitious agents is responsible for the positive result.

For retroviral vectors, testing for RCR is required for cell banks, viral vector production lots, and any resultant ex vivo product lots (see the FDA's *Draft Guidance for Industry: Supplemental Guidance on Testing for Replication Competent Retrovirus in Retroviral Vector Based Gene Therapy Products and During Follow-Up of Patients in Clinical Trials Using Retroviral Vectors*, October 2000). Standard assays have been designed to detect replication-competent murine leukemia virus (MLV). The pathogenesis and potential long-term toxicity of low-level amphotropic MLV in human beings is not known. Methods commonly used to detect RCR include an amplification of virus titer by application of product to a replication-permissive cell line such as *Mus dunni*. Because infection is limited by the ability of a virus to reach the cells through Brownian motion, procedures (e.g., centrifugation and filtration) that physically bring the virus into contact with the cells may be used to enhance detection. However, high-titer recombinant vector can interfere with the detection of low-level RCR and this interference may be enhanced through such methods. Infected cells are passaged several times to allow viral replication. Culture medium is harvested at the end of the culture period and RCR detected by using an indicator cell line. If the product is an amphotropic MLV, RCR may be detected by using a feline cell-based PG4 S+L- assay, a mink cell-based MiCi S+L- assay, or a marker rescue assay. In S+L- assays, the RCR expresses proteins that lead to transformation and subsequent plaque formation on the monolayer. In a marker rescue assay, RCR infects a cell line that expresses a retroviral vector encoding a marker gene such as  $\beta$ -galactosidase, drug resistance, or a fluorescent protein. The vector is packaged by the proteins supplied to it in trans by the RCR. The potentially vector-laden supernatant is transferred to naive target cells that are then screened for expression of the marker vector.

Testing for RCR is performed by cocultivation of the cell line or amplification of vector supernatant with an RCR replication-permissive cell line, typically *Mus dunni*, for several passages. Culture medium is harvested at the end of this cocultivation process and applied to an appropriate indicator cell line as described above. It is important to note that artifacts may be generated during the cocultivation assay by expression of an endogenous virus in the permissive cell line or through fusion if the vector-producing cell line is cultured directly with a marker rescue cell line. In addition, cocultivation may not be possible for ex vivo cell products that have specific culture requirements or limited culture life spans.

Methodologies for testing the presence of RCR in crude, purified bulk or final vector products are not specified. The FDA has deposited a reference standard of an amphotropic hybrid MLV with the ATCC. This viral stock has been assigned a label titer and should be used in assay validation. Method validation should demonstrate the ability to reproducibly detect a single RCR particle in individual product types because the product and its related impurities can interfere with the detection of RCR. Currently there are no acceptable limits for RCR contamination in products. Any product lot found to contain RCR cannot be used for human use.

Reference standards for assessing RCV in other viral vectors including ecotropic, xenotropic or pseudotyped MLV, adenovirus, and lentivirus have not been developed. Amplification and detection of replication-competent HIV, especially its pseudotyped variants, may warrant special containment and handling procedures.

Additional safety testing usually focuses on methods similar to those described under [Biotechnology-Derived Articles](#) (1045), in Safety Tests—Biologics under [Biological Reactivity Tests](#). [In Vivo](#) (88), and under [Sterility Tests](#) (71). For viral gene therapies produced using a human cell line, performance of the in vitro adventitious agent bioassays using 3 cell lines is recommended on either the bulk or final product. For adenoviral vectors, specific tests for adeno-associated virus are also recommended on either the bulk or final product. For adeno-associated virus, specific tests for adenovirus and herpesvirus are recommended on either the bulk or final product.

#### nonviral gene therapy products

Safety testing usually focuses on methods similar to those described under [Biotechnology-Derived Articles](#) (1045), in Safety Tests—Biologics under [Biological Reactivity Tests](#). [In Vivo](#) (88), and under [Sterility Tests](#) (71). However, the General Safety test is not required for therapeutic DNA plasmid products (even if formulated). Safety testing should be performed on nonviral formulated material. If the shelf life of the formulated nonviral therapy is very short, then the components should be tested individually.

#### Dose-Defining Assays general considerations

An assay that precisely measures the amount of the product is referred to as a dose-defining assay, and it is selected on the basis of its precision and accuracy. An assay that measures therapeutic activity of the product is referred to as a potency assay and it is designed to measure product function. The design of the assay is dependent upon the type of product. In the case of drugs, the assays measuring the amount of active ingredient (dose) are referred to as strength assays.

Product dose can be defined as the concentration or amount of the drug product administered to the patient and it is typically measured as product mass. For cell and gene therapy products, attributes such as viable cell number, milligrams of plasmid or antisense oligonucleotide, or the viral particle number are often used to define the dose of the product.

#### cell therapy products

Cell therapy products may be dosed on the basis of enumeration of one or more cell populations. For ex vivo gene therapy, dose may be based on cell number as well as level of expression of the gene product. For products in the form of a homogeneous, single-cell suspension, viable cell number is the most frequently used assay. Such assays may include enumeration of all cells, total nucleated cells, or another subset of cells. Viability assays are usually based on a cell's ability to exclude a supravital dye, such as trypan blue. Results are expressed as the number of cells that exclude the dye and are therefore considered viable. The compound 7-AAD, a red-fluorescing compound that binds to nuclear proteins and is also excluded by viable cells, may be incorporated into flow-cytometric methods for simultaneous determination of viability and cell-identity markers.

Cell counting may be performed rapidly by manual or automated methods. Manual cell counting by visual enumeration of cells in a hemacytometer chamber is a readily available technique with acceptable accuracy, but a lower degree of precision than most automated methods. Typical instruments for automated cell counting provide reproducible enumeration of nonnucleated cells (e.g., erythrocytes and platelets) and nucleated cells and differential counting of the nucleated cells into mononuclear and polymorphonuclear leukocyte populations. Further discrimination of specific cell populations usually requires cell-surface phenotype analysis by flow-cytometric or other methods (see Cell Therapy Products under Identity). The proportion of a specific subpopulation of cells may be determined by FACS analysis or by flow cytometry.

An example of a cell enumeration assay is the enumeration of CD34-positive (CD34+) hematopoietic progenitor cells, the number being expressed as the number of cells per recipient's body weight. In numerous studies this measurement has been shown to predict hematologic reconstitution following myelosuppressive or ablative therapy in autologous or allogeneic hematopoietic transplantation.

For products that contain cells in a nonhomogeneous suspension, such as cells that form a two- or three-dimensional structure, alternative measures for cell enumeration, such as total area of a cell sheet, wet weight, total protein, and total DNA, have been used. If such measures are used to determine product dose, then supplemental tests must be performed to demonstrate therapeutic activity.

#### viral and nonviral gene therapy products

Particle concentration is a commonly used measure for viral vector product dose. Particle concentration may be measured by physical, biophysical, or in vitro cell-based assays. For example, quantitation of purified adenoviral particles may be determined by using the optical density of a solution of virus in 0.1% (w/v) sodium dodecyl sulfate (SDS) solution, at 260 nm, because a relationship between absorption and particle concentration has been published for adenovirus. The particle number concentration is equivalent to the product of the absorbance at 260 nm in a 1-cm cell, the dilution factor, and  $1.1 \times 10^{12}$  particles.<sup>2</sup> Other methods to determine particle concentration include particle counting by electron microscopy and integration of viral peak area against an authenticated reference standard in an anion-exchange resin-based high-pressure liquid chromatographic (HPLC) assay.

Virus concentration can also be assessed through the measurement of selected structural proteins with known molecular masses and known copy numbers within the virion. For this method, the virus has to be lysed, and the structural proteins have to be separated by using an appropriate, high-recovery chromatographic procedure (e.g., reverse-phase HPLC). The chromatographic separation and the identity and the purity of the selected structural protein has to be verified during assay validation by methods such as SDS polyacrylamide gel electrophoresis (SDS-PAGE), peptide sequencing, and mass spectroscopy. The selected structural proteins have to be quantified, for example, by integrating chromatographic peaks at 214 nm and comparing the area to an authenticated reference standard. The virus concentration can then be calculated based on the molecular mass, the copy number, and the measured mass of the protein. Very importantly, the virus concentration can be estimated simultaneously for multiple structural proteins, allowing the use of this assay in relatively impure virus preparations. This method has been applied to adenovirus and should be applicable to other viral vector types.

Biophysical methods of determining particle number include direct quantitation of vector nucleic acid by radiolabeled-probe hybridization and indirect quantitation by amplification of template nucleic acid (e.g., PCR and RT-PCR) or by signal amplification (e.g., branched-chain DNA using multiple-probe hybridization).

In cases where biophysical methods are not available, bioassays that measure gene-vector titer have been used. These involve infection, transfection, or transduction of a susceptible cell line *in vitro*, followed by some measure of the product uptake. Methods for quantitation or estimation of the number of infection, transfection, or transduction events include plaque-forming unit assays, tissue culture infectious dose, 50% (TCID<sub>50</sub>) assays based on cytopathic effect or immunofluorescent detection of an expressed vector protein, or a quantitative DNA-hybridization assay. Examples are as follows.

For retroviral or lentiviral gene therapy products or AAVs that carry a selectable marker (e.g., that for neomycin resistance) or a reporter gene (e.g.,  $\beta$ -galactosidase) in addition to the therapeutic gene, the infectious titer is commonly determined by measuring the number of transduced or infected cells expressing these nontherapeutic proteins. Vector titer is typically reported as the number of colony-forming units (cfu) per mL for cells transduced with viral vectors containing drug-resistance markers and selected for growth in drug-containing medium. Titer based on  $\beta$ -galactosidase can be expressed in terms of blue (cfu) per mL after staining and counting the cells that convert the  $\beta$ -galactosidase substrate X-Gal into a blue chromophore. For vectors without a marker gene, quantitation of transduction has been measured precisely by using quantitative PCR.

Most nonviral gene therapy products contain plasmid DNA and their usual measure of dose is the DNA mass. The DNA mass may be determined in the formulated state, and, if recombinant protein is included in the formulation, the total combined mass of all formulation components based on a specific ratio can be used. DNA concentrations greater than 500 ng per mL are most simply determined by using optical density measurement at 260 nm. This method is not generally applicable to lipid-formulated DNA. Because RNA and proteins also have significant absorbances at 260 nm, other analyses must be performed to demonstrate that there is minimal contamination with RNA, protein, or residual host-cell chromosomal DNA. Dyes that specifically bind to double-stranded DNA allow the DNA concentrations of less than 500 ng per mL to be measured accurately when calculated against an authenticated DNA standard curve. PicoGreen is one such fluorescent dye and it is minimally affected by single-stranded DNA, RNA, proteins, salts, and detergents. The fluorescent dye Hoechst 33258 also binds to both double-stranded and single-stranded DNA and it can be used to determine DNA concentrations as low as 0.3 ng per mL. The Hoechst 33258 does not bind to protein or RNA and it can accurately determine the DNA concentrations in crude samples.

Methods, such as capillary electrophoresis, employing an authenticated reference material, can also be used to determine the strength of nonviral and antisense-oligonucleotide products.

#### Potency

##### general considerations

Potency is defined as the therapeutic activity of the drug product. Together with dose, potency defines the biological activity of each lot (see General Considerations under Dose-Defining Assays). Potency may be assessed through *in vitro* or *in vivo* bioassays. It is not uncommon for these assays to have coefficients of variation between 30% and 50%. These assays require a well-defined, representative reference material that can be used as a positive control for the assay. The positive control serves to qualify the performance of an individual assay. Potency assay development should focus on characterizing and controlling variability. The high-precision assays are more effective tools in monitoring product quality. Information about potency-assay variability should be incorporated into the stability study design and the proposed statistical approach to assignment of expiration date (see Stability).

#### cell therapy products

Functional assays that can be performed on cellular products are application-related and include viable cell number and a wide range of colony-forming assays, proliferative assays, cell-to-target killing assays, and assays that quantitate gene expression following gene transduction. For hematopoietic progenitor cells prepared from marrow, peripheral blood, or cord blood, traditional colony-forming assay quantitates committed progenitor cells such as colony-forming unit-granulocyte-macrophage (CFU-GM); this assay has been correlated with clinical engraftment outcomes in some studies. More recently, process-monitoring programs incorporate assays such as the long-term culture-initiating cell (LTCIC) assay or the *in vivo* animal models such as competitive repopulation in immunodeficient mice to monitor the activity of the most primitive hematopoietic stem cells. In the case of cells intended for structural repair, proliferation under a set of defined ex vivo conditions may be used as the potency assay. If the cells release an enzyme or active molecule, a potency assay could be based on the units of enzymatic activity or on the total of active molecules released. For instance, the production of insulin in response to changes in glucose levels could be the basis of a potency assay for cells intended to treat diabetes.

Patient-specific products, such as autologous cancer vaccines that elicit an *in vivo* immune response, present a challenge in demonstrating therapeutic activity in an *in vitro* or *in vivo* assay system. Assessment of potency in these circumstances is currently the subject of public-policy debate. Novel approaches to measuring potency, such as the correlation of clinical outcome to other characterization tests such as identity tests, may be appropriate and should be discussed with regulatory authorities early in development. For example, the ability to determine specific cell-surface identity markers by employing flow-cytometric techniques or vital stains may be an acceptable measurement of potency if properly validated and correlated with clinical outcome.

## viral and nonviral gene therapy products

Bioassays employed to measure the potency of viral and nonviral gene therapy products generally involve infection, transfection, or transduction of a susceptible cell line in vitro, followed by some functional measure of the expressed gene of interest. Functional assays for the therapeutic gene (e.g., those measuring enzyme activity and cytokine activity) should generally be used instead of analytical methods such as enzyme-linked immunosorbent assay (ELISA), HPLC, or FACS, which provide information about the level of expression but only infer function. In addition, for viral vectors, infectious titer measurements by themselves are generally not considered an adequate measure of product potency. The design and ultimate suitability of an assay system for determining product potency will depend on the relationship between the intended human target cell in vivo and the following: (1) the transduction or transfection efficiency of the cell line used in vitro (2) the protein expression levels, and (3) the duration of expression required for the therapeutic effect.

In vivo tests may also be used to measure vector-product potency. Readouts may be based on a response per animal (e.g., blood levels of therapeutic protein 24 hours after treatment) or a group response rate (e.g., percentage of animals that elicited an immune response or survived virus challenge). The availability of an appropriate in vivo test system will depend on the vector-host range (for viral vectors), the pharmacokinetics and biodistribution of the vector and its resultant gene product relative to its human counterpart, and the time frame required to observe the therapeutic effect or surrogate. Issues of cost, facilities, validation, and ethics will determine the practicality of an in vivo potency test.

### Purity

#### general considerations

Analytical methods that separate, isolate, and specifically quantify the intended active product components determine product purity. Impurities are either product- or process-related components that can be carried through to the final product. The manufacturing and purification process should be optimized to consistently remove impurities while retaining product activity. The requirement to test for a particular impurity for product lot release will depend on the following: (1) the demonstrated capability of the manufacture and purification process to remove or inactivate the impurity through process validation, and (2) the toxicity potential associated with the impurity.

Examples of process-related impurities associated with cell and gene therapy products include residual production-medium components (e.g., FBS, antibiotics, cytokines, and *Escherichia coli* chromosomal DNA in a plasmid product), ancillary products used in downstream processing (e.g., nucleases such as DNase I), and residual moisture for lyophilized vector products. Impurities may be biactive (e.g., cytokines and hormones) or immunogenic (e.g., product aggregates, degradation products, plasmid-selection markers, and nonhuman-derived proteins) or they may have other deleterious effects (e.g., they may compete with the product) if administered at a dose equal to that of the product. Product-related impurities are specific to each product type. Examples include differentiated cells in a stem-cell therapy product, nicked plasmid forms in nonviral products, and defective or immature virus particles in retroviral or adenoviral vector products. Analytical methodologies to assess purity require quantitation or physical separation of intended product from its impurities. Common sense should drive the need to quantify specific impurities. It may be possible to validate the manufacturing process to the extent that specific lot-release testing for impurities will be very limited. An emphasis may be placed on demonstrating the consistency of the product-impurity profile.

Testing for impurities is often extensive during product characterization and process validation when the consistency of the manufacturing and purification process is being demonstrated. Testing for impurities as part of lot-release testing should reflect the safety risks associated with the impurity and the ability of the process to consistently remove that impurity.

#### cell therapy products

One measure of purity is the percentage of viable cells in the total cell population. Another measure is the percentage of transduced cells or the percentage of cells with a specific marker. If an entire population of cells is the therapeutic agent, methods should determine the relative amounts of each subpopulation. Limits should be defined for each cell subpopulation. These assays may be based on immunological methods utilizing flow cytometry or DNA-hybridization dot blot analysis. Additional tests for process contaminants are performed depending on the specifics of the manufacturing process. For example, a quantitative ELISA for residual serum proteins may be required. If the cells are genetically modified during manufacture, then testing for residual vector may need to be performed.

For gene-modified cell therapies, determining the purity of the cell therapy product depends on the availability of reagents and methods to distinguish therapeutic cells from the other cells present in the product. As in the case of gene therapy products, gene-modified cells can be distinguished from the unmodified cells on the basis of expression of the transgene. FACS using an antibody that detects the therapeutic protein or fluorescent probes that detect expressed RNA allow the separation and quantitation of the transgene expressing and nonexpressing cells. By adding an antibody to a cell-specific phenotypic marker and by using a double-sorting technique, FACS can be used to further identify the subpopulation of cells that are modified.

Endotoxin testing is also required. Biomaterials used with cell therapy products should also be tested for their biocompatibility.

#### viral gene therapy products

Product-related impurities for viral vectors include aggregates and defective and immature particles that may be produced during the manufacture or purification of the recombinant vector. Aggregates of vector may form if the product is highly concentrated, stored under certain conditions (e.g., under certain pH or temperature), or reconstituted after lyophilization. Assays to detect aggregates include particle size analysis by laser light-scattering and the use of nonreducing, nondenaturing PAGE, followed by staining of the gel or transfer and detection of viral proteins by Western blot analysis. Sedimentation rate analysis also allows separation of aggregates from monomers based on size. Optical density analyses of light-scattering are also used to assess vector aggregation.

Defective particles are viral particles that do not contain the appropriate recombinant genome, that is, they contain some other nucleic acid or contain no genome at all, or the vector has some missing, defective, or otherwise altered structural component that impairs its ability to transduce a cell. For viral vector systems that have capsomeric symmetry, which requires the appropriate nucleic acid incorporation for configuration, empty particles may be readily distinguished from those carrying genomes. For enveloped viruses, empty particles may not be as readily separated from those with encapsidated nucleic acid.

For some viral vector products, active viral particles may be separated from defective particles by using analytical HPLC. Anion-exchange resins have been used to separate active adenovirus from defective virus particles. However, this method might not be useful for an adenoviral vector purified by anion-exchange chromatography unless the resin for the assay is different from that used during manufacture. Depending on the nature of the viral vector and its nonactive or defective forms, other methods of separation, such as equilibrium centrifugation in a cesium chloride density gradient, may need to precede the quantitation of the active particle. Ideally, the method of separation will allow quantitation.

Defective particles that carry a noncell-derived oncogenic gene or other undesirable genes may pose a special concern. For example, in murine-based retroviral packaging cell lines, small viral elements called VL30 sequences can be packaged in about one third of all particles. Assays may need to be developed to quantify specific defective particles if they are known to be present in quantities sufficient to pose a safety concern.

Virus quality and the comparability of preparations can also be assessed by measuring selected structural proteins with known molecular masses and known copy numbers within the virion. For this method, the virus is lysed, and the structural proteins are separated by using reverse-phase HPLC or some other high-recovery chromatographic procedure. The chromatographic separation should be validated and the identity of the selected structural proteins verified by methods such as SDS-PAGE, peptide sequencing, or mass spectroscopy. One can fingerprint the batch based on quantification of the selected structural proteins and comparison to a reference standard. When the method incorporates the use of mass spectroscopy, impurities such as structural variants can also be identified. For adenovirus preparations, some precursor and most mature virion proteins can be monitored, thus allowing monitoring of the product and of the immature virion forms.

Host cell-derived proteins may be considered impurities for some viral vector products and may be separated and quantified by PAGE or HPLC or detected by amino acid analysis, Western blot, or immunoassay-based methods. However, for enveloped viruses such as retroviruses, host cell-derived membrane proteins are an integral part of the product. In those vector systems, it may be difficult to determine the presence of contaminating exogenous host-derived proteins.

Presence of specific process-related impurities depends on the manufacture and purification process of each vector or product type. However, most products will need to be tested for residual endotoxin (see [Bacterial Endotoxins Test \(85\)](#)). Acceptable limits of endotoxins have been determined and can be directly applied to viral vector products.

Although genomic DNA derived from continuous cell substrates used to manufacture biological product has been considered historically as potentially tumorigenic, recent studies suggest that the risks are very low. However, every attempt should be made during process development to reduce contaminating DNA levels. The need to test for residual DNA as part of product lot release should be evaluated on a case-by-case basis and may be dependent upon the size distribution of the DNA, its association with the product or its formulation

...ponents, and the route of administration of the product. Quantitative PCR assays have been developed to analyze the amount of residual host-cell DNA by using primers designed to amplify evolutionarily conserved and abundant target sequences, such as 18S for 293 cells.

Quantitation of residual serum components such as bovine serum albumin (BSA) can be achieved by using ELISA and a BSA reference standard. Specific functional or immunological methods may need to be developed for other ancillary products including other culture media or purification process components such as cytokines or enzymes (e.g., nucleases such as DNase I or benzonase).

#### nonviral gene therapy products

Testing is usually performed on the individual components, the plasmid DNA, the lipid or lipoplex components and (recombinant) protein components if any are present in the formulation. Plasmid DNA is characterized for a variety of impurities including residual host-cell DNA, residual RNA, and residual protein. Residual protein testing is frequently included in lot-release testing. Optical density ratios, usually the ratio of the measurement at 260 nm to that at 280 nm, are frequently used in purity specifications for plasmid DNA.

In addition, the plasmid DNA should also be characterized with regard to its form. Plasmid DNA forms include monomeric supercoiled, relaxed monomer, and linear forms. The profile of forms needs to be monitored for product consistency. Additionally, it may be possible to correlate form with *in vivo* transfection behavior. While monomeric supercoiled plasmid has been shown to be more efficient than relaxed monomer, linear, or multimeric forms of the plasmid in transfecting cell lines *in vitro*, *in vitro* transfection has been shown to not always predict *in vivo* behavior. Formulation, delivery method, and route may impact *in vivo* transfection. Agarose gel electrophoresis can resolve these forms of plasmid, which are then detected by UV after ethidium bromide staining. This method provides information about the relative levels of the plasmid forms, but it is not highly quantitative for the individual species. Analytical anion-exchange HPLC can be used as a quantitative assay for monomeric supercoil and percentage of other forms, including concatamers. Other sophisticated methods, such as capillary zone electrophoresis, linear-flow dichroism, and atomic-force microscopy have been proposed as replacements for agarose gel analysis. Until they are validated, these analytical methods may be more appropriate for characterization studies in support of process development and validation rather than for lot-release testing. The appropriate methods for lot release will depend on what effect these alternate plasmid forms have on the product potency. Many of these methods, such as HPLC, are also applicable to the assessment of the purity of antisense-oligonucleotide products and the determination of the level of by-products.

Tests for process-related impurities, such as cesium chloride, must also be conducted. In the case of antisense-oligonucleotide products, residual solvents must be quantified. Lipid and lipoplex formulation components must also be tested for their chemical purity. Testing for specific chemical impurities is commonly performed by using gas chromatography-mass spectroscopy (GC-MS), high-pressure liquid chromatography (HPLC), or thin-layer chromatography (TLC) methods.

If protein is part of the formulated complex, then the protein must also be tested for purity. The methods outlined under [Biotechnology-Derived Articles](#) (1045) or under [Biotechnology-Derived Articles—Capillary Electrophoresis](#) (1053), [Biotechnology-Derived Articles—Isoelectric Focusing](#) (1054), and [Biotechnology-Derived Articles—Polyacrylamide Gel Electrophoresis](#) (1056) are relevant.

Bacterial protein, DNA, RNA, and endotoxins are the major types of host-derived process contaminants. Standard protein assays (e.g., Lowry, Bradford, or Coomassie), PAGE followed by silver staining or Western blot analysis, or ELISA can be used to detect residual host protein in the nanogram range. Host chromosomal DNA may be detected by slot blot hybridization (detection in picogram range) or by PCR using highly conserved target sequences (e.g., 18S for *Escherichia coli*). However, low background may be unavoidable in PCR-based assays because the recombinant polymerases used for the amplification of target also contain residual bacterial DNA. PAGE or agarose gel electrophoresis followed by fluorescent dye staining may be used to detect residual RNA. Quantitation may not be required given the labile nature of RNA and the low-level toxicity associated with it.

Certain antibiotics, such as kanamycin, that may be used during the fermentation process must be removed during the process, and validation of the process or lot-release testing must be performed to confirm removal during the purification of the plasmid. HPLC is one method that can be used to detect low-level residual antibiotic.

#### lyophilized viral and nonviral vector products

Residual moisture may affect the stability of a lyophilized vector product. The FDA's Guideline for the Determination of Residual Moisture in Dry Biological Products (January 1990) recommends a 1% residual moisture level, although data indicating no adverse effects on product stability at higher levels will be considered acceptable. Residual moisture levels can be determined by using a standard method (see [Water Determination](#) (921)) that is compatible with the formulated product.

#### Identity

##### general considerations

Lot-release testing for cell and gene therapy products must include an identity test. This test serves to specifically identify the product. The complexity of the identity test will depend on the nature of the specific product and the array of products being manufactured. For example, more extensive and rigorous testing may be performed for an autologous gene-modified cell therapy product at a facility where multiple patient products are manufactured than for a viral vector product produced at a site that manufactures a single vector product.

#### cell therapy products

Cell therapy identity tests must be relevant to the cell type and manipulations applied during processing. Differential surface markers (for instance, CD3, CD4, CD34, and CD45) are frequently used to ascertain product identity. Flow-cytometric immunoassay methods are the most common means of detecting and quantifying these markers. In this type of assay, a sample of the cells is stained with fluorescently labeled antibodies directed against specific identity markers and then passed as a single cell suspension in front of a laser source. Identification and quantitation of particular cell subsets is accomplished by multiparameter analysis, usually of size and granularity (measured by forward and side light-scattering) and of one or more identity markers (measured by emitted fluorescence). Simultaneous quantitation of cell viability can be performed by adding 7-amino-actinomycin D (7-AAD) to cell suspensions marked with antibodies conjugated to green (e.g., FITC) or orange (e.g., phycoerythrin) fluorescent compounds.

Analyses, such as isoenzyme analyses, employing biochemical markers are also used. For example, isoenzyme analyses are used to confirm species in the case of xenotransplants. Cell morphology can be used if it can distinguish specific cell types or unique function. Morphology can be combined with doubling-time parameters to better distinguish different cell types.

#### viral gene therapy products

Restriction enzyme mapping and sequencing of the transcription unit DNA are the most commonly used approaches to establishing the identity of viral vectors for characterization purposes. PCR-based methods, restriction enzyme mapping, and transgene expression-based immunoassays are most commonly used to confirm the identity during lot-release testing.

#### nonviral gene therapy products

Restriction enzyme mapping is the most common identity method for plasmid-DNA and antisense-oligonucleotide products. The number of enzymes used to create the vector fingerprint will vary with the complexity of the DNA and the degree of similarity between multiple products. If lipids, lipoplex agents, or proteins are used to formulate the DNA, then their identity must also be tested. Lipids and lipoplex chemicals may be identified by procedures used for traditional pharmaceuticals, such as GC-MS, TLC, and the like. Protein components of the formulation may be identified by peptide mapping or other means outlined under [Biotechnology-Derived Articles—Isoelectric Focusing](#) (1054), [Biotechnology-Derived Articles—Peptide Mapping](#) (1055), and [Biotechnology-Derived Articles—Polyacrylamide Gel Electrophoresis](#) (1056).

#### STABILITY

##### General Considerations

The shelf lives of cell and gene therapy products will vary widely, depending on the nature of the product, its intended clinical use, its specific attributes, and the recommended storage, packaging, and shipping conditions. Therefore, it is difficult to draft uniform guidelines regarding stability-study duration and testing frequency applicable to all gene and cell therapy products. In all cases, the stability study should be designed on the basis of scientifically sound principles and approaches and a comprehensive understanding of the final therapeutic product and its intended use. Stability of in-process hold steps, cell and virus banks, critical raw materials, and reference standards also needs to be assessed. A well-designed and executed stability program will provide a high degree of assurance that the product is stable within the specified shelf life.

For viral and nonviral vector gene therapy products and cell therapy products that are not patient-specific, the selection of batches to support license application and final-product labeling should be carried out in accordance with the principles of stability testing, such as those described in ICH guideline Q5C, presented under [Quality of Biotechnological Products: Stability Testing of Biotechnological/Biological Products](#) (1049). Stability data should also be collected for bulk material and other in-process points if material is stored before final processing and filling.

Nonviral DNA plasmid vectors are often formulated with specific mixtures of lipids, proteins, or lipoconjugates to form liposomes or encapsulated complexes. Depending on the formulation used, a shelf life of hours to years can be attained. Where a product has a short shelf life, the final formulation may need to be prepared at the clinic just before administration. Instability is frequently observed as aggregation and precipitation. Formation and stability of the formulated complex must be established through validation studies during product development. Stability data should also be collected for major components of the formulated complex, such as the lipids, the liposomes, and the DNA itself.

For many patient-specific cell products including transduced products, each product is unique and often only one lot is prepared for a single patient. In general, the lots tend to be of small volumes, sometimes less than 10 mL, and they may involve products that cannot be frozen and hence have short shelf lives (between 24 and 72 hours) as the cells continue to metabolize their medium. Protocols to establish stability of patient-specific therapy should use materials from multiple donors and at least three lots. Well-characterized banked primary cells may be used in the validation of storage, shipping, and expiration dating if the donors have a range of profiles expected for the patient population to which the therapy will ultimately be directed. The stability of the product under the holding conditions at the medical center should be validated.

#### Stability-Protocol Development

Formal stability studies to support licensure as well as early phase product stability information gathering should be detailed in a written plan that describes how stability data will be collected and analyzed to support the expiration period of the product. Protocols should follow the format recommended in existing guidelines and include the scope, storage conditions, number of lots to be tested, test schedule, assays to be used, data analysis, and product specifications. Any assay used in a formal stability study for licensure must be validated before the study begins. The specific study design should take into account the reasonably expected possibilities the product may encounter (see Accelerated and Most Appropriate Challenge Conditions) and it should incorporate the latest knowledge in the biological sciences while addressing existing regulatory requirements. For instance, if the final formulation of the product is performed at the clinical site, stability studies on this final formulation should be done to establish the time and conditions under which the product can be held.

Stability studies must verify that the storage conditions maintain the purity and potency of the product, so that the product administered to the patient is still capable of satisfying the stability specifications. These specifications may differ from the release specifications. However, stability specifications must be verified with clinical data. Stability assessment should include assessment of product functionality (potency). The potency assay often has a high degree of inherent variability. Measuring and calculating the decay of product activity by employing the standard statistical methodologies may require multiple, frequent sampling intervals over an extended period of time and may require analysis of more than three production lots to compensate for the variability of the assays. Initial studies to establish a provisional expiration date must be conducted prior to administration to the first patient. Initial studies are also useful for determining which assays are stability-indicating, that is, the best indicators of product degradation. Because existing compendial methods do not address the unique characteristics of cell and gene therapy products, the development of assays that would address these unique characteristics is encouraged.

#### Accelerated and Most Appropriate Challenge Conditions

The stability-indicating profile of a cell or gene therapy product may vary with time under the influence of a wide variety of environmental conditions, including temperature, extremes in physiological storage conditions, and light. Multifactorial degradation pathways must be considered in the development of a program investigating the effects of these parameters on the stability of the products. Studies should include conditions that are outside of the specified storage ranges, that is, challenge conditions such as those encountered during periods of abnormal storage, shipping, or handling. Examples include brief incubator malfunctions, incubator or cold storage failure, periods of extreme temperature fluctuation due to shipping to hot or cold climates, hypobaric conditions experienced in the cargo hold of a commercial airliner, or temperatures likely to be encountered in the surgical suite. A short exposure to an environmental condition well outside of an established limit and a long exposure to an environmental condition just outside of an established acceptable range may be equally detrimental. The slow and constant rate of product degradation at a specified temperature may increase if a different set of storage conditions is applied. The effect of light on the stability-indicating profile should be investigated if it is scientifically warranted. Special attention should be given to products stored in fluids containing light-sensitive or reactive components that may give rise to cytotoxic by-products.

Studies analogous to accelerated aging studies typically used in pharmaceutical stability-monitoring programs are also useful to determine how the product degrades and which assays are stability-indicating. These studies can be the same as some of those mentioned in the preceding paragraph. Other studies include placing a product at 37° or at 18°, while its normal storage temperature is 25 ± 2°, or placing a lyophilized product in a high-humidity environment. Such studies should be performed before formal stability studies begin, so that the formal studies incorporate the validated stability-indicating assays into the protocol.

#### STORAGE AND SHIPPING

##### General Considerations

The storage conditions are chosen to preserve the purity and potency of the product so that the specifications for the product are maintained throughout storage, shipping, and handling at the clinic. Initial studies must be conducted prior to patient administration to determine acceptable storage, shipping, and handling conditions. The initial storage and shipping conditions need not be those envisioned for the commercial product. They should ensure that the product specifications are maintained beyond the initially proposed expiration dating. For products with short shelf lives, storage and shipping conditions, even within a medical center, need to be considered together because shipping constitutes the bulk of storage time after manufacturing. Special consideration should be given to the ability of gas to permeate the shipping container, especially if the cell or gene therapy product is stored or shipped on dry ice. Once stability-indicating methods are developed and the final storage and shipping conditions are chosen, these conditions are validated as discussed under Stability.

Most products with limited shelf lives will be shipped by using reliable overnight courier systems. In some cases, some critical products are hand-carried onto commercial aircraft.

Special permission must be obtained by commercial carriers if scanning by airport X-ray equipment is to be avoided. Cargo shipping studies should be designed during the development of packaging systems to identify stresses to which biological products may be subjected. Bracing and insulating materials should then be chosen and validated to provide a packaging system that will alleviate the extreme conditions of shipping.

#### Cell Therapy Products

**Cryopreservation**— Cryopreservation is the main mode used for the long-term storage of cells, that is, storage of cells for periods longer than 1 year. (See also Suspensions under Formulation of Cell Therapy Products.) The rate of cooling for the cell solutions is important because of the mechanical and dehydration injuries resulting from the formation and growth of ice crystals. The ideal temperatures are dependent upon the type of cells being cryopreserved and the concentration of the cryopreservative. The optimal cooling rate for most cells is between 1° and 3° per minute. Controlled-rate freezers, which can reproducibly produce this optimal cooling rate, are critical when large numbers of vials or large volumes of cells in bags are being frozen. Once cooled to below freezing, cells need to be stored at temperatures below -130°. This can be achieved with electric freezers or with liquid nitrogen. Storage of cells in the vapor phase of a liquid nitrogen freezer reduces the risk of cross-contamination with other material in the freezer. However, a map of freezer temperatures needs to be generated so that cells are not stored so far from the liquid nitrogen that they are subjected to temperatures above -130° as the liquid nitrogen evaporates or during the opening of the freezer. Some cells can be stored at -80° if the cells are to be used within a few weeks.

**Thawing**— Thawing is performed fairly rapidly. If a small amount of cells is to be reinfused or transplanted, DMSO does not need to be removed from the suspension, because most cell preparations can be concentrated adequately to keep the DMSO concentration within tolerable limits. DMSO use has two effects on cells after thawing: cells may clump if damaged, and DMSO reduces cell viability in minutes. If the DMSO needs to be removed or cells need to be concentrated for administration, the defrosted cell suspension is generally serially diluted to avoid osmotic shock and resuspended in a protein-containing medium. Cell viability and potency are generally determined after thawing, but the information may not influence the clinical use of the material.

**Frozen Products**— Frozen cell therapy products are shipped to the medical center on dry ice or in liquid nitrogen dry shippers. Dry shippers may be preferable because temperature is more readily maintained during shipping. Dry ice and liquid nitrogen are both considered hazardous materials during shipping. Storage conditions at the clinic need to be defined. Most

pharmacies do not have access to liquid nitrogen freezers. At best, they have mechanical freezers capable of maintaining the temperature at  $-70^{\circ}\text{C}$ . Clinics that have cell-processing centers or are involved with bone marrow transplantation have liquid nitrogen freezers. If further processing, for example, defrosting and administering, of the cell product is performed at the clinic, the storage conditions and expiration date for the product should be specified. Often the laboratory that is handling the cells and the clinic that will administer the product have to closely collaborate because cells in a concentrated suspension survive for only a few hours.

**Unfrozen Products**— Other cell therapy products are stored unfrozen. Because cells continue to metabolize during storage, their expiration period is typically between 24 and 96 hours.

The expiration date can be extended to several weeks by increasing the volume of storage medium, by reducing the storage temperature, or by attaching a series of bags or compartments that allow the medium to be exchanged without breaching the sterility of the system. These products are shipped in insulating containers with refrigerant packs to maintain a defined temperature range. To stabilize the excursions from these defined and validated temperature ranges, well-designed container configurations with dense foam insulation, which protects the product from shifts in external environmental temperatures, are used. The product purity and potency should not be affected over practical shipment intervals, that is, intervals of 24 to 96 hours, either at higher or lower temperatures. However, if potency may be affected, the shipping box configuration must be re-engineered to maintain optimal potency for the longest possible shipping periods. The product itself should be placed in a lightproof, leakproof container with adequate physical support to ensure stability and prevention of leakage during typical conditions of shipment.

#### Gene Therapy Products

Most gene therapy products can be lyophilized or formulated by means similar to those employed for many recombinant protein products or cell therapy products. These storage formulations typically have expiration periods longer than one year and no unusual shipping requirements. Nonviral gene therapy products, which may be unstable in their final formulation, can have similar expiration periods if they are stored in a multiple-vial kit with the nucleic acid in one vial and a carrier, such as lipids, in the other. The final formulation is performed at the medical center just before administration.

#### LABELING

Product labeling is regulated by the FDA and compliance with existing regulations is required. Labeling of cell and gene therapy products as regulated biologics will be subject to these regulations. For biologics and devices (21 CFR 610 Subpart G and 21 CFR 801, respectively), the labeling requirements are separated into container labeling and package labeling requirements. Both the container label and the package label must include the expiration date. If the container is packaged, then the recommended storage conditions are included on the package label. If the container is not packaged, the recommended storage conditions and all other requirements of a package label must appear on the container label. Labeling must also comply with relevant national and international requirements.

If antibiotics are used in the cell processing and therefore may be present in the final product, the labeling should reflect this. For cell therapy products that must be applied to the patient in a particular physical orientation, labeling that indicates the correct orientation should be apparent even after the package is opened. Similarly, if a device should be only grafted in a defined area, that area should be made readily apparent by labeling that is evident once the package is opened. Unless the product has been screened for pathogenic or microbial contaminants prior to release, appropriate biohazard labeling may be required. For products with very short shelf lives, expiration dating will require adjustment and correction for time zones to provide the user an accurate assessment of shelf life. Clinical procedures will be scheduled around these crucial time frames. For patient-specific products, the patient's full name, initials, or a combination of these will need to appear on the labeling, in addition to lot designation, to ensure that the product will be administered to the appropriate patient.

#### REGULATIONS, STANDARDS, AND NEW METHODOLOGIES

##### Summary of Regulations and Standards

The technologies involved in cell and gene therapy products have been widely documented in the literature and are rapidly evolving. These products can be regulated as drugs, biologics, or devices, or not regulated at all, depending on how they are manufactured and used. The novel approaches permitted by these technologies may make it difficult to determine which FDA centers will be involved in their regulation and the FDA has advised manufacturers to seek clarification in the early stages of development. Regulation is the same as that for biotechnology-derived products. The general requirements are described primarily in the 21 CFR. The federal government has issued many general guidelines as Points to Consider or Guidance documents (see [www.fda.gov](http://www.fda.gov)). ICH guidance documents for many of the quality-related areas are directly relevant to qualifying cell and gene therapy products (see [www.ifpma.org/ich1.html](http://www.ifpma.org/ich1.html)) and some of these documents are reproduced in USP 25 as general informational chapters. National Institutes of Health (NIH) has published Guidelines for Research Involving Recombinant DNA Molecules (see <http://www4.od.nih.gov/oba/rac/guidelines/guidelines.html> for text of the document and its amendments) that require NIH review of research, including clinical research or trials, conducted or sponsored by institutions receiving NIH funding. These guidelines apply to many gene therapy products. AATB has developed guidelines for sourcing allogeneic tissue. Public Health Service (PHS), with input from the NIH, FDA, the Centers for Disease Control and Prevention (CDC), and Health Research Services Administration (HRSA), has developed guidelines for the use of xenogeneic-derived products (Draft Public Health Service (PHS) Guideline on Infectious Disease Issues in Xenotransplantation, August 1996). In addition, ASTM is also developing standards for tissue-engineered medical products.

##### Need for New Methodologies

Cost-effective commercialization of cell and gene therapy products requires the development and validation of new methodologies to assess product quality. USP will adopt such new methodologies when they have been properly validated. Similarly, if reference standards or reference materials are needed and available, they could be included in the USP inventory to allow comparative analysis among various clinical trials or to serve as points of reference by manufacturers of these products for raw materials, process components, and process impurities.

#### DEFINITION OF TERMS

**ADENOVIRUS**— Virus belonging to the family Adenoviridae of DNA viruses having a nonenveloped virion with 252 capsomeres and a diameter between 70 and 90 nm; a single linear molecule of double-stranded DNA (36 to 38 kb); at least 10 structural ether-resistant and acid-stable proteins; virions are released by cell destruction.

**ADENOVIRUS-ASSOCIATED VIRUS (AAV)**— Human parvovirus contains a single-stranded DNA genome and depends on helper viruses (adenovirus, herpesvirus, or vaccinia-virus) for replication. Without coinfection, the wild-type virions integrate at a specific site on chromosome 19 and remain latent.

**ADVENTITIOUS AGENT**— A foreign substitute that is introduced accidentally or inadvertently; not natural or hereditary (as in microbial, chemical, or biochemical contamination of a purified substance).

**ALLOGENEIC**— From an unrelated member of the same species; from the same species, but with a different genotype.

**AMPHOTROPIC VIRUS**— A virus that infects and replicates in cells from multiple species.

**ANCILLARY PRODUCTS**— Components used during manufacturing that should not be present in the final product. Examples: growth factors, cytokines, monoclonal antibodies, cell separation devices, media, and media components.

**ANTISENSE THERAPY**— The use of antisense oligonucleotides (a complementary segment to RNA) to control or inhibit gene expression.

**APHERESIS**— Procedure of withdrawing blood from a donor, removing select components (e.g., platelets or leukocytes), and retransfusing the remainder into the donor.

**AUTologous**— From one's own body.

**BASE PAIR**— Two nucleotide bases on different strands of the nucleic acid molecule that bond together.

**BIOASSAY**— Measurement of the effectiveness of a compound by its effect on animals or cells in comparison with a standard preparation. (See also Potency.)

**BIOLOGICAL PRODUCT**— Any virus, therapeutic serum, toxin, antitoxin, or analogous product applicable to the prevention, treatment, or cure of diseases or injuries in humans. (The term analogous product has been interpreted to include essentially all biotechnology-derived products and procedures including gene therapy, transgenics, and somatic cell therapy.)

TECHNOLOGY— Any technique that uses living organisms (or parts of organisms) to make or modify products, to improve plants or animals, or to develop microorganisms for specific uses. The newer definition refers to the industrial and pharmaceutical use of rDNA, cell fusion, novel bioprocessing techniques, and gene therapy.

B LYMPHOCYTES (B cells)—A class of lymphocytes that produce antibodies and are derived from the bone marrow.

BONE MARROW CELLS—A variety of undifferentiated cells (stem cells) and differentiated cells (lymphocytes, granulocytes, erythrocytes, and platelets) found in the internal cavities of bones or bone marrow.

BONE MARROW TRANSPLANTATION—Transplantation of bone marrow cells that are capable of maintaining the hematological functions indefinitely. Technique used in the treatment of immunological disorders (severe combined immune deficiencies such as ADA deficiency), hematological disorders (anemia), metabolic disorders (Gaucher's disease), and malignant diseases (leukemia, lymphoma, or solid tumor).

CD34—Cluster of Differentiation cell-surface marker 34. CD34 is a protein that distinguishes stem and progenitor cells from more mature blood cells.

CELL LINES—Cells that are derived from primary culture embryos, tissue, or organs. Such cell lines may have a finite life span or be immortalized (made to replicate indefinitely).

CELL THERAPY—Therapy that uses whole cells to treat a disease, condition, or injury.

CGMP—Current good manufacturing practice. The FDA outlines CGMP in the 21 CFR and in the Federal Register and its Points to Consider.

CHONDROCYTES—Cells that produce the components of cartilage.

CLONAL—Genes, cells, or entire organisms derived from and genetically identical to a single common ancestor gene, cell, or organism.

CLONOGENIC ASSAY—Procedure based on the ability to give rise to a clone of cells.

COMPLEMENTARY DNA (cDNA)—DNA synthesized from an mRNA rather than a DNA template. It is used for cloning or as a DNA probe for locating specific genes.

CYTOKINE—Any factor that acts on cells; usually a protein that promotes growth.

CYTOPLASM—Cellular material that is within the cell membrane and surrounds the nucleus.

CYTOTOXIC—Able to cause cell death.

DENDRITIC CELL—Cells that sensitize T cells to antigens.

DIFFERENTIATION—A process of biochemical and structural changes by which cells become specialized in form and function.

DIPLOID CELL—A cell with two complete sets of chromosomes (see Haploid Cell).

ECOTROPIC VIRUS—A virus that infects and replicates in cells from only the original host species.

ELECTROPORATION—Physical means of gene transfer (using a brief electrical field), involving creation of temporary pores in cell membrane to introduce DNA.

ELISA—Enzyme-linked immunosorbent assay. An immunoassay that utilizes an enzyme-labeled antigen or antibody to detect the binding of a molecule to a solid matrix.

ENDOTHELIAL CELLS—Epithelial cells of mesodermal origin that line the internal cavities of the body, such as heart and blood and lymph vessels.

ENGRAFTMENT—Process whereby cells, tissues, or organs are implanted or transplanted into another organism. Refers both to the mechanical and the biological processes necessary to have a fully functional graft.

ENVELOPED VIRUSES—Viruses containing a lipoprotein bilayer surrounding the capsid and acquired by budding through the cell membrane of the host cells.

EPIDERMAL—Pertaining to the outermost and nonvascular layer of the skin derived from embryonic ectoderm.

EPISOMAL—Pertaining to any accessory extrachromosomal genetic material.

EPITHELIAL CELLS—Cells from the linings of various organs. Examples: respiratory, intestinal, or vascular epithelial cells.

EXTRACORPOREAL—Situated or performed outside of the body.

EX VIVO—Procedure performed outside of the living organism.

FIBROBLASTS—Connective tissue cells that have the capacity to produce collagen.

FLUORESCENCE-ACTIVATED CELL SORTER (FACS)—A machine that sorts cells based on fluorescent markers attached to them.

FORMULATED—Prepared in accordance with a prescribed method or conditions.

FUSION—Joining of the membrane of two cells, creating a daughter that contains some of the same properties from each parent cell. It is used in making hybridoma cells in which antibody-producing cells are fused to mouse myeloma cells.

G-418—The antibiotic used to select and isolate cells that contain neomycin-resistance gene.

GENE CONSTRUCT—Expression vector that contains the coding sequence of the protein and the necessary elements for its expression.

GENE THERAPY—Therapy that uses DNA to treat a disease or condition. FDA defines gene therapy products as products containing genetic material administered to modify or manipulate the expression of genetic material to alter the biological properties of living cells.

GENOME—Total hereditary material of a cell.

GERM CELL—Reproductive cell (sperm or egg), gamete, or sex cell.

GRAFT VERSUS HOST DISEASE (GVHD)—Rejection of the transplanted tissue by the host. It is the leading cause of patient death when mismatched allogeneic tissue is used.

GRAFT VERSUS LEUKEMIA (GVL)—Rejection of host leukemia cells by donor T cells.

GRANULOCYTE—One of three types of white blood cells. These cells digest bacteria and other parasites.

GRANULOCYTE-MACROPHAGE COLONY-STIMULATING FACTOR (GM-CSF)—A natural hormone that stimulates white blood cell production, particularly that of granulocytes and monocytes.

GROWTH FACTORS—Factors responsible for regulatory cell proliferation, function, and differentiation.

HAPLOID—A cell with half the usual number of chromosomes or only one chromosome set. Germ cells are haploid.

HELPER VIRUS—Aids the development of a defective virus by supplying or restoring the activity of a viral gene or by enabling the defective virus to form a functional envelope.

HEMACYTOMETER—A device used to manually count cells.

HEMATOPOIETIC—Pertaining to or affecting the formation of blood cells.

HEPATOCYTES—The predominant cell type in the liver that has an important role in metabolism and is a source of serum proteins. These cells are generally not dividing, but when injured they can divide and regenerate until the injured cells are replaced.

HERPES SIMPLEX VIRUS (HSV)—A DNA virus that is a member of the family Herpesviridae. It can infect both warm- and cold-blooded vertebrates by contact between moist mucosal

surfaces.

HUMAN LEUKOCYTE ANTIGEN (HLA)—Proteins controlled by the major histocompatibility complex. These proteins play a key role in determining transplant compatibility.

HUMORAL—Pertaining to elements found in body fluids (for example, humoral immunity and neutralizing antibodies).

HYBRIDIZATION DOT BLOT (DNA or RNA)—A technique for detecting, analyzing, and identifying protein; similar to the Western blot but without electrophoretic separation of proteins.

IMMUNOASSAY—Technique for identifying substances based on the use of antibodies.

IMMUNOFLUORESCENCE—Technique for identifying a fluorescent label.

IMMUNOGEN—Substance capable of inducing an immune response; a form of antigen that induces immune response, as opposed to a tolerogen that induces tolerance.

IMPLANTATION VS TRANSPLANTATION—Implantation is the insertion or grafting of a biological, living, inert, or radioactive material into the body. Transplantation is the grafting of tissues from the patient's own body or from another person's body.

INSERTIONAL MUTAGENESIS—A type of mutation that is caused by the insertion of a foreign gene into a host-cell chromosome. There are multiple negative consequences of such an event, including death of a cell if an essential gene is inactivated or predisposition to cancer if a tumor suppressor gene is inactivated.

INTEGRATION—Assimilation of genetic material (DNA) into the chromosome of a recipient cell.

INTERLEUKIN (IL)—Lymphokine that regulates the growth and development of white blood cells. More than 12 have been identified.

INTRABODIES—Intracellular antibodies that are not secreted and that are designed to bind and inactivate target molecules inside cells.

IN VIVO—Procedure performed in the living organism.

IN VITRO—Procedure performed outside of the living organism. It may involve cells or tissues derived from the organisms.

ISLET CELLS— $\beta$ -islet cells of the pancreas that secrete insulin.

ISOGENIC—Of the same genotype.

KERATINOCYTES—Differentiated epidermal cells that constitute the top layer of cells in the skin.

LEUKEMIA—Malignant neoplasm of the blood-forming tissues.

LINEAGE (COMMITTED PROGENITOR CELLS, DIFFERENTIATED CELLS)—Specific path of cell differentiation that can be traced to a single cell of origin.

LIPOPLEX—A formulation of lipids and polymers and/or proteins.

LIPOSOME—A spherical lipid bilayer enclosing an aqueous compartment.

LYMPHOKINE—Class of soluble proteins produced by white blood cells that play a role in the immune response.

LYMPHOMA—Form of cancer that affects the lymphatic tissue.

MICROINJECTION—Physical means of gene transfer involving a direct injection of the cell with a syringe and a needle.

MACROPHAGE—Any of many forms of mononuclear phagocytes that are found in tissues and arise from hematopoietic stem cells in the bone marrow.

MOCK RUN—A test run that deliberately omits some critical reagents.

MONOCLONAL ANTIBODIES—Antibodies that are derived from a single cell clone.

MONOCYTES—One of the three types of white blood cells. They are precursors to macrophages.

MYELOSUPPRESSION—Inhibition of bone marrow activity resulting in depletion of red cells, white cells, and platelets.

MYOCYTES—Fundamental cell units in the muscle. Target cells for insertion of genes that encode secretory proteins.

NEOMYCIN—Antibiotic derived from Streptomyces fradiae.

NAKED DNA—Isolated, purified, and uncomplexed DNA (no protein or lipid).

OLIGONUCLEOTIDE—A polymer consisting of a small number of nucleotides, usually 5 to 30.

ONCOGENES—Genes associated with neoplastic proliferation (cancer) following a mutation or perturbation in their expressions.

ONCOGENIC—Cancer-causing.

OSTEOGENIC CELLS—Derived from or involved in the growth or repair of bone.

PACKAGING CELL LINE—Cell line that produces all of the proteins required for packaging and production of viral vectors in an active form, but does not produce replication-competent virus.

p53GENE—Gene whose mutation is the most common alteration observed in human cancers. It is not required for normal development, but the lack of this gene highly increases the potential risk of cancer.

PARVOVIRUS—DNA viruses of the family Parvoviridae. Host range includes many vertebrate species.

PERCUTANEOUS—Performed through the skin. An example of a percutaneous procedure is the injection of an agent or removal of a tissue (sample for biopsy) with a needle.

PERITONEAL MESOTHELIUM—Lining of the peritoneal cavity consisting of a single sheet of cells covering a broad surface. It has abundant lymphatic drainage and permits diffusion of macromolecules.

PLASMID—A small circular form of DNA that carries certain genes and is capable of replicating independently in a host cell.

POLYCLONAL—Derived from a population of cells consisting of many clonal types.

PROCESS VALIDATION—Means for providing documentation that the manufacturing process is controlled, reproducible, and capable of consistently producing a product that meets predetermined specifications.

PRODUCER CELL LINE—An established cell line used to produce virus vectors, often at a large scale.

POLYMERASE CHAIN REACTION (PCR)—Technique to amplify a target DNA or RNA sequence of nucleotides by several hundred thousand-fold.

POTENCY—A quantitative measure of biological activity based on the attribute of the product linked to the relevant biological properties.

PROGENITOR CELL—Parent or ancestral cell, usually one that is already committed to differentiate into a specific type or lineage of cells.

PROMOTER—DNA sequence that is located at the front of a gene and controls gene expression. It is required for binding of RNA polymerase to initiate transcription.

RADIOIMMUNOASSAY (RIA)—Technique for quantifying a substance by measuring the reactivity of radioactively labeled forms of the substance.

RECOMBINANT-DNA— DNA produced by joining fragments of DNA from different sources by in vitro manipulations.

REPLICATION-COMPETENT VIRUS— A virus that can complete an entire replication cycle without a need for a helper virus; an autonomously replicating virus.

RESTRICTION ENDONUCLEASE— An endonuclease that recognizes a specific sequence of bases within double-stranded DNA.

RETROVIRUS— A virus that contains the reverse transcriptase, which converts viral RNA into DNA that then integrates into the host cell in a form called a provirus.

SERUM-FREE— Refers to cell growth medium that lacks a serum component.

SOMATIC CELLS— Cells other than the germ cells.

S PHASE— Part of the cell cycle during which DNA replication occurs.

STEM CELL— Immortal cell that is capable of proliferating and differentiating into different types of specialized cells. Each major tissue system is thought to have its own putative stem cell.

STROMAL— Refers to cellular support elements that contain essential nutrients or growth factors.

SUPRAVITAL DYE— A dye that stains only living cells.

SUSPENSION CULTURE— Cells capable of growth in suspension, not requiring substrate (attachment) on which to grow.

T CELLS— Lymphocytes that acquire functional repertoires and the concept of self in the thymus and are responsible for cell-mediated immunity. There are several subsets of T cells (helper T cells, suppressor T cells, and cytotoxic T cells).

TCID<sub>50</sub> ASSAY— Tissue Culture Infectious Dose, 50% Assay. An assay measuring the amount of product at which 50% of culture cells in the assay are killed (cytopathic effect) or are expressing a vector protein.

TRANSDUCTION— Transfer and expression of genetic material into a cell by means of a virus or phage vector.

TRANSFECTION— Transfer of DNA into cells by physical means such as by calcium phosphate coprecipitation.

TRANSGENE— Refers to the foreign or therapeutic DNA that is part of a vector construct.

TUMORGENICITY— Having the properties of inducing a malignant neoplasm.

VECTOR— The agent (plasmid, virus, or liposome—protein or DNA—protein complex) used to introduce DNA into a cell.

VIABILITY— State of being alive and functional.

VIRION— An elementary viral particle consisting of genetic material (nucleocapsid) and a protein covering.

VIRUS— Submicroscopic organism that contains genetic information necessary for reproduction. It is an obligate intracellular parasite.

WESTERN BLOT— An electroblotting method in which proteins are transferred from a gel to a thin, rigid support (e.g., nitrocellulose membrane) and detected by binding radioactively labeled antibody or antibody coupled to an enzyme, allowing use of a precipitating chromogenic or chemiluminescent substrate.

XENOGENEIC— From a different species.

XENOTRANSPLANTATION— Transplantation of organs from one species to another (e.g., from pigs to humans).

ZOONOSIS— The disease of animals transmitted to humans via routine exposure to or consumption of the source material.

#### ABBREVIATIONS

AABB	American Association of Blood Banks
7-AAD	7-amino-actinomycin D
AATB	American Association of Tissue Banks

## 1048 QUALITY OF BIOTECHNOLOGICAL PRODUCTS: ANALYSIS OF THE EXPRESSION CONSTRUCT IN CELLS USED FOR PRODUCTION OF r-DNA DERIVED PROTEIN PRODUCTS<sup>1</sup>

### I. INTRODUCTION

This document presents guidance regarding the characterization of the expression construct for the production of recombinant DNA (r-DNA) protein products in eukaryotic and prokaryotic cells. The document is intended to describe the types of information that are considered valuable in assessing the structure of the expression construct used to produce r-DNA derived proteins. The document is not intended to cover the entire quality aspect of r-DNA derived medicinal products.

The expression construct is defined as the expression vector containing the coding sequence of the recombinant protein. Segments of the expression construct should be analyzed using nucleic acid techniques in conjunction with other tests performed on the purified recombinant protein for assuring the quality and consistency of the final product. Analysis of the expression construct at the nucleic acid level should be considered as part of the overall evaluation of quality, taking into account that this testing only evaluates the coding sequence of a recombinant gene and not the translational fidelity nor other characteristics of the recombinant protein, such as secondary structure, tertiary structure, and posttranslational modifications.

### II. RATIONALE FOR THE ANALYSIS OF THE EXPRESSION CONSTRUCT

The purpose of analyzing the expression construct is to establish that the correct coding sequence of the product has been incorporated into the host cell and is maintained during culture to the end of production. The genetic sequence of recombinant proteins produced in living cells can undergo mutations that could alter the properties of the protein with potential adverse consequences to patients. No single experimental approach can be expected to detect all possible modifications to a protein. Protein analytical techniques can be used to assess the amino acid sequence of the protein and structural features of the expressed protein due to posttranslational modifications such as proteolytic processing, glycosylation, phosphorylation, and acetylation. Data from nucleic acid analysis may be useful because protein analytical methods may not detect all changes in protein structure resulting from mutations in the sequence coding for the recombinant protein. The relative importance of nucleic acid analysis and protein analysis will vary from product to product.

Nucleic acid analysis can be used to verify the coding sequence and the physical state of the expression construct. The nucleic acid analysis is performed to ensure that the expressed protein will have the correct amino acid sequence, but is not intended to detect low levels of variant sequences. Where the production cells have multiple integrated copies of the expression construct, not all of which may be transcriptionally active, examination of the transcription product itself by analysis of m-RNA or c-DNA may be more appropriate than analysis of genomic DNA. Analytical approaches that examine a bulk population of nucleic acids, such as those performed on pooled clones or material amplified by the polymerase chain reaction, may be considered as an alternative to approaches that depend on selection of individual DNA clones. Other techniques could be considered that allow for rapid and sensitive confirmation of the sequence coding for the recombinant protein in the expression construct.

The following sections describe information that should be supplied regarding the characterization of the expression construct during the development and validation of the production system. Analytical methodologies should be validated for the intended purpose of confirmation of sequence. The validation documentation should, at a minimum, include estimates of the limits of detection for variant sequences. This should be performed for either nucleic acid or protein sequencing methods. The philosophy and recommendations for analysis expressed in this document should be reviewed periodically to take advantage of new advances in technology and scientific information.

### III. CHARACTERIZATION OF THE EXPRESSION SYSTEM

#### A. Expression Construct and Cell Clone Used to Develop the Master Cell Bank (MCB)

The manufacturer should describe the origin of the nucleotide sequence coding for the protein. This should include identification and source of the cell from which the nucleotide sequence was originally obtained. Methods used to prepare the DNA coding for the protein should be described.

The steps in the assembly of the expression construct should be described in detail. This description should include the source and function of the component parts of the expression construct, e.g., origins of replication, antibiotic resistance genes, promoters, enhancers, and whether or not the protein is being synthesized as a fusion protein. A detailed component map and a complete annotated sequence of the plasmid should be given, indicating those regions that have been sequenced during the construction and those taken from the literature. Other expressed proteins encoded by the plasmid should be indicated. The nucleotide sequence of the coding region of the gene of interest and associated flanking regions that are inserted into the vector, up to and including the junctions of insertion, should be determined by DNA sequencing of the construct.

A description of the method of transfer of the expression construct into the host cell should be provided. In addition, methods used to amplify the expression construct and criteria used to select the cell clone for production should be described in detail.

#### B. Cell Bank System

Production of the recombinant protein should be based on well-defined MCB and Working Cell Banks (WCB). A cell bank is a collection of ampules of uniform composition stored under defined conditions, each containing an aliquot of a single pool of cells. The MCB is generally derived from the selected cell clone containing the expression construct. The WCB is derived by expansion of one or more ampules of the MCB. The cell line history and production of the cell banks should be described in detail, including methods and reagents used during culture, in vitro cell age, and storage conditions. All cell banks should be characterized for relevant phenotypic and genotypic markers, which could include the expression of the recombinant protein or presence of the expression construct.

The expression construct in the MCB should be analyzed as described below. If the testing cannot be carried out on the MCB, it should be carried out on each WCB.

Restriction endonuclease mapping or other suitable techniques should be used to analyze the expression construct for copy number, for insertions or deletions, and for the number of integration sites. For extrachromosomal expression systems, the percent of host cells retaining the expression construct should be determined.

The protein coding sequence for the recombinant protein product of the expression construct should be verified. For extrachromosomal expression systems, the expression construct should be isolated and the nucleotide sequence encoding the product should be verified without further cloning. For cells with chromosomal copies of the expression construct, the nucleotide sequence encoding the product could be verified by recloning and sequencing of chromosomal copies. Alternatively, the nucleic acid sequence encoding the product could be verified by techniques such as sequencing of pooled c-DNA clones or material amplified by the polymerase chain reaction. The nucleic acid sequence should be identical, within the limits of detection of the methodology, to that determined for the expression construct as described in section III.A., and should correspond to that expected for the protein sequence.

#### C. Limit for In Vitro Cell Age for Production

The limit for in vitro cell age for production should be based on data derived from production cells expanded under pilot plant-scale or full-scale conditions to the proposed in vitro cell age or beyond. Generally, the production cells are obtained by expansion of the WCB; the MCB could be used to prepare the production cells with appropriate justification.

The expression construct of the production cells should be analyzed once for the MCB as described in section III.B., except that the protein coding sequence of the expression construct in the production cells could be verified by either nucleic acid testing or analysis of the final protein product. Increases in the defined limit for in vitro cell age for production should be supported by data from cells that have been expanded to an in vitro cell age that is equal to or greater than the new limit for in vitro cell age.

#### IV. CONCLUSION

The characterization of the expression construct and the final purified protein are both important to ensure the consistent production of a r-DNA derived product. As described above, analytical data derived from both nucleic acid analysis and evaluation of the final purified protein should be evaluated to ensure the quality of a recombinant protein product.

#### GLOSSARY OF TERMS

##### Expression Construct

The expression vector that contains the coding sequence of the recombinant protein and the elements necessary for its expression.

##### Flanking Control Regions

Noncoding nucleotide sequences that are adjacent to the 5' and 3' end of the coding sequence of the product that contain important elements that affect the transcription, translation, or stability of the coding sequence. These regions include, e.g., promoter, enhancer, and splicing sequences, and do not include origins of replication and antibiotic resistance genes.

##### Integration Site

The site where one or more copies of the expression construct is integrated into the host cell genome.

##### In Vitro Cell Age

Measure of time between thaw of the MCB vial(s) to harvest of the production vessel measured by elapsed chronological time in culture, by population doubling level of the cells, or by passage level of the cells when subcultivated by a defined procedure for dilution of the culture.

##### Master Cell Bank (MCB)

An aliquot of a single pool of cells that generally has been prepared from the selected cell clone under defined conditions, dispensed into multiple containers, and stored under defined conditions. The MCB is used to derive all working cell banks. The testing performed on a new MCB (from a previous initial cell clone, MCB, or WCB) should be the same as for the MCB unless justified.

##### Pilot Plant Scale

The production of a recombinant protein by a procedure fully representative of and simulating that to be applied on a full commercial manufacturing scale. The methods of cell expansion, harvest, and product purification should be identical except for the scale of production.

##### Relevant Genotypic and Phenotypic Markers

Those markers permitting the identification of the strain of the cell line that should include the expression of the recombinant protein or presence of the expression construct.

##### Working Cell Bank (WCB)

The WCB is prepared from aliquots of a homogeneous suspension of cells obtained from culturing the MCB under defined culture conditions.

1 This guideline was developed within the Expert Working Group (Quality) of the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) and has been subject to consultation by the regulatory parties, in accordance with the ICH process. This document has been endorsed by the ICH Steering Committee at Step 4 of the ICH process, November 29, 1995. At Step 4 of the process, the final draft is recommended for adoption to the regulatory bodies of the European Union, Japan and the USA. This guideline was published in the Federal Register on February 23, 1996 (61 FR 7006) and is applicable to drug and biological products. Although this guideline does not create or confer any rights for or on any person and does not operate to bind FDA or the industry, it does represent the agency's current thinking on the production of r-DNA derived protein products. For additional copies of this guideline, contact the Drug Information Branch, HFD-210, CDER, FDA, 5600 Fishers Lane, Rockville, MD 20857 (Phone: 301-827-4573) or the Manufacturers Assistance and Communication Staff (HFM-42), CBER, FDA, 1401 Rockville Pike, Rockville, MD 20852-1448. Send one self-addressed adhesive label to assist the offices in processing your request. An electronic version of this guidance is also available via Internet using the World Wide Web (WWW) (connect to the CDER Home Page at <http://www.fda.gov/cder> and go to the "Regulatory Guidance" section).

Auxiliary Information— Please [check for your question in the FAQs](#) before contacting USP.

1049 QUALITY OF BIOTECHNOLOGICAL PRODUCTS: STABILITY TESTING OF BIOTECHNOLOGICAL/ BIOLOGICAL PRODUCTS<sup>1</sup>

#### I. INTRODUCTION (1)

The guidance stated in the ICH harmonized tripartite guideline entitled "Stability Testing of New Drug Substances and Products" (issued by ICH on October 27, 1993) applies in general to biotechnological/biological products. However, biotechnological/biological products have distinguishing characteristics to which consideration should be given in any well-defined testing program designed to confirm their stability during the intended storage period. For such products in which the active components are typically proteins and/or polypeptides, maintenance of molecular conformation and, hence, of biological activity, is dependent on noncovalent as well as covalent forces. The products are particularly sensitive to environmental factors such as temperature changes, oxidation, light, ionic content, and shear. To ensure maintenance of biological activity and to avoid degradation, stringent conditions for their storage are usually necessary.

The evaluation of stability may necessitate complex analytical methodologies. Assays for biological activity, where applicable, should be part of the pivotal stability studies. Appropriate physicochemical, biochemical, and immunochemical methods for the analysis of the molecular entity and the quantitative detection of degradation products should also be part of the stability program whenever purity and molecular characteristics of the product permit use of these methodologies.

With these concerns in mind, the applicant should develop the proper supporting stability data for a biotechnological/biological product and consider many external conditions that can affect the product's potency, purity, and quality. Primary data to support a requested storage period for either drug substance or drug product should be based on long-term, real-time, real-condition stability studies. Thus, the development of a proper long-term stability program becomes critical to the successful development of a commercial product. The purpose of this document is to give guidance to applicants regarding the type of stability studies that should be provided in support of marketing applications. It is understood that during the review and evaluation process, continuing updates of initial stability data may occur.

## II. SCOPE OF THE ANNEX (2)

The guidance stated in this annex to "Stability Testing of New Drug Substances and Products" applies to well-characterized proteins and polypeptides, their derivatives and products of which they are components, and which are isolated from tissues, body fluids, cell cultures, or produced using recombinant deoxyribonucleic acid (r-DNA) technology. Thus, the document covers the generation and submission of stability data for products such as cytokines (interferons, interleukins, colony-stimulating factors, tumor necrosis factors), erythropoietins, plasminogen activators, blood plasma factors, growth hormones and growth factors, insulins, monoclonal antibodies, and vaccines consisting of well-characterized proteins or polypeptides. In addition, the guidance outlined in the following sections may apply to other types of products, such as conventional vaccines, after consultation with the appropriate regulatory authorities. The document does not cover antibiotics, allergenic extracts, heparins, vitamins, whole blood, or cellular blood components.

## III. TERMINOLOGY (3)

For the basic terms used in this annex, the reader is referred to the "Glossary" in "Stability Testing of New Drug Substances and Products." However, because manufacturers of biotechnological/biological products sometimes use traditional terminology, traditional terms are specified in parentheses to assist the reader. A supplemental glossary is also included that explains certain terms used in the production of biotechnological/biological products.

## IV. SELECTION OF BATCHES (4)

### A. Drug Substance (Bulk Material) (4.1)

Where bulk material is to be stored after manufacture, but before formulation and final manufacturing, stability data should be provided on at least three batches for which manufacture and storage are representative of the manufacturing scale of production. A minimum of 6 months stability data at the time of submission should be submitted in cases where storage periods greater than 6 months are requested. For drug substances with storage periods of less than 6 months, the minimum amount of stability data in the initial submission should be determined on a case-by-case basis. Data from pilot-plant scale batches of drug substance produced at a reduced scale of fermentation and purification may be provided at the time the dossier is submitted to the regulatory agencies with a commitment to place the first three manufacturing scale batches into the long-term stability program after approval.

The quality of the batches of drug substance placed into the stability program should be representative of the quality of the material used in preclinical and clinical studies and of the quality of the material to be made at manufacturing scale. In addition, the drug substance (bulk material) made at pilot-plant scale should be produced by a process and stored under conditions representative of that used for the manufacturing scale. The drug substance entered into the stability program should be stored in containers that properly represent the actual holding containers used during manufacture. Containers of reduced size may be acceptable for drug substance stability testing provided that they are constructed of the same material and use the same type of container/closure system that is intended to be used during manufacture.

### B. Intermediates (4.2)

During manufacture of biotechnological/biological products, the quality and control of certain intermediates may be critical to the production of the final product. In general, the manufacturer should identify intermediates and generate in-house data and process limits that assure their stability within the bounds of the developed process. Although the use of pilot-plant scale data is permissible, the manufacturer should establish the suitability of such data using the manufacturing scale process.

### C. Drug Product (Final Container Product) (4.3)

Stability information should be provided on at least three batches of final container product representative of that which will be used at manufacturing scale. Where possible, batches of final container product included in stability testing should be derived from different batches of bulk material. A minimum of 6 months data at the time of submission should be submitted in cases where storage periods greater than 6 months are requested. For drug products with storage periods of less than 6 months, the minimum amount of stability data in the initial submission should be determined on a case-by-case basis. Product expiration dating should be based upon the actual data submitted in support of the application. Because dating is based upon the real-time/real-temperature data submitted for review, continuing updates of initial stability data should occur during the review and evaluation process. The quality of the final container product placed on stability studies should be representative of the quality of the material used in the preclinical and clinical studies. Data from pilot-plant scale batches of drug product may be provided at the time the dossier is submitted to the regulatory agencies with a commitment to place the first three manufacturing scale batches into the long-term stability program after approval. Where pilot-plant scale batches were submitted to establish the dating for a product and, in the event that the product produced at manufacturing scale does not meet those long-term stability specifications throughout the dating period or is not representative of the material used in preclinical and clinical studies, the applicant should notify the appropriate regulatory authorities to determine a suitable course of action.

### D. Sample Selection (4.4)

Where one product is distributed in batches differing in fill volume (e.g., 1 milliliter (mL), 2 mL, or 10 mL), unitage (e.g., 10 units, 20 units, or 50 units), or mass (e.g., 1 milligram (mg), 2 mg, or 5 mg), samples to be entered into the stability program may be selected on the basis of a matrix system and/or by bracketing.

Matrixing, i.e., the statistical design of a stability study in which different fractions of samples are tested at different sampling points, should only be applied when appropriate documentation is provided that confirms that the stability of the samples tested represents the stability of all samples. The differences in the samples for the same drug product should be identified as, for example, covering different batches, different strengths, different sizes of the same closure, and, possibly, in some cases, different container/closure systems. Matrixing should not be applied to samples with differences that may affect stability, such as different strengths and different containers/closures, where it cannot be confirmed that the products respond similarly under storage conditions.

Where the same strength and exact container/closure system is used for three or more fill contents, the manufacturer may elect to place only the smallest and largest container size into the stability program, i.e., bracketing. The design of a protocol that incorporates bracketing assumes that the stability of the intermediate condition samples are represented by those at the extremes. In certain cases, data may be needed to demonstrate that all samples are properly represented by data collected for the extremes.

## V. STABILITY-INDICATING PROFILE (5)

On the whole, there is no single stability-indicating assay or parameter that profiles the stability characteristics of a biotechnological/biological product. Consequently, the manufacturer should propose a stability-indicating profile that provides assurance that changes in the identity, purity, and potency of the product will be detected.

At the time of submission, applicants should have validated the methods that comprise the stability-indicating profile, and the data should be available for review. The determination of which tests should be included will be product-specific. The items emphasized in the following subsections are not intended to be all-inclusive, but represent product characteristics that should typically be documented to demonstrate product stability adequately.

### A. Protocol (5.1)

The dossier accompanying the application for marketing authorization should include a detailed protocol for the assessment of the stability of both drug substance and drug product in support of the proposed storage conditions and expiration dating periods. The protocol should include all necessary information that demonstrates the stability of the biotechnological/biological product throughout the proposed expiration dating period including, for example, well-defined specifications and test intervals. The statistical methods that should be used are described in the tripartite guideline on stability.

### B. Potency (5.2)

When the intended use of a product is linked to a definable and measurable biological activity, testing for potency should be part of the stability studies. For the purpose of stability testing of the products described in this guideline, potency is the specific ability or capacity of a product to achieve its intended effect. It is based on the measurement of some attribute of the product and is determined by a suitable *in vivo* or *in vitro* quantitative method. In general, potencies of biotechnological/biological products tested by different laboratories can be compared in a meaningful way only if expressed in relation to that of an appropriate reference material. For that purpose, a reference material calibrated directly or indirectly against the corresponding national or international reference material should be included in the assay.

Potency studies should be performed at appropriate intervals as defined in the stability protocol and the results should be reported in units of biological activity calibrated, whenever possible, against nationally or internationally recognized standards. Where no national or international reference standards exist, the assay results may be reported in in-house derived units using a characterized reference material.

In some biotechnological/biological products, potency is dependent upon the conjugation of the active ingredient(s) to a second moiety or binding to an adjuvant. Dissociation of the active ingredient(s) from the carrier used in conjugates or adjuvants should be examined in real-time/real-temperature studies (including conditions encountered during shipment). The assessment of the stability of such products may be difficult because, in some cases, in vitro tests for biological activity and physicochemical characterization are impractical or provide inaccurate results. Appropriate strategies (e.g., testing the product before conjugation/binding, assessing the release of the active compound from the second moiety, in vivo assays) or the use of an appropriate surrogate test should be considered to overcome the inadequacies of in vitro testing.

#### C. Purity and Molecular Characterization (5.3)

For the purpose of stability testing of the products described in this guideline, purity is a relative term. Because of the effect of glycosylation, deamidation, or other heterogeneities, the absolute purity of a biotechnological/biological product is extremely difficult to determine. Thus, the purity of a biotechnological/biological product should be typically assessed by more than one method and the purity value derived is method-dependent. For the purpose of stability testing, tests for purity should focus on methods for determination of degradation products.

The degree of purity, as well as the individual and total amounts of degradation products of the biotechnological/biological product entered into the stability studies, should be reported and documented whenever possible. Limits of acceptable degradation should be derived from the analytical profiles of batches of the drug substance and drug product used in the preclinical and clinical studies.

The use of relevant physicochemical, biochemical, and immunochemical analytical methodologies should permit a comprehensive characterization of the drug substance and/or drug product (e.g., molecular size, charge, hydrophobicity) and the accurate detection of degradation changes that may result from deamidation, oxidation, sulfoxidation, aggregation, or fragmentation during storage. As examples, methods that may contribute to this include electrophoresis (SDS09Page, immunoelectrophoresis, Western blot, isoelectrofocusing), high-resolution chromatography (e.g., reversed-phase chromatography, gel filtration, ion exchange, affinity chromatography), and peptide mapping.

Wherever significant qualitative or quantitative changes indicative of degradation product formation are detected during long-term, accelerated, and/or stress stability studies, consideration should be given to potential hazards and to the need for characterization and quantification of degradation products within the long-term stability program. Acceptable limits should be proposed and justified, taking into account the levels observed in material used in preclinical and clinical studies.

For substances that cannot be properly characterized or products for which an exact analysis of the purity cannot be determined through routine analytical methods, the applicant should propose and justify alternative testing procedures.

#### D. Other Product Characteristics (5.4)

The following product characteristics, though not specifically relating to biotechnological/biological products, should be monitored and reported for the drug product in its final container:

Visual appearance of the product (color and opacity for solutions/suspensions; color, texture, and dissolution time for powders), visible particulates in solutions or after the reconstitution of powders or lyophilized cakes, pH, and moisture level of powders and lyophilized products.

Sterility testing or alternatives (e.g., container/closure integrity testing) should be performed at a minimum initially and at the end of the proposed shelf life.

Additives (e.g., stabilizers, preservatives) or excipients may degrade during the dating period of the drug product. If there is any indication during preliminary stability studies that reaction or degradation of such materials adversely affect the quality of the drug product, these items may need to be monitored during the stability program.

The container/closure has the potential to affect the product adversely and should be carefully evaluated (see below).

### VI. STORAGE CONDITIONS (6)

#### A. Temperature (6.1)

Because most finished biotechnological/biological products need precisely defined storage temperatures, the storage conditions for the real-time/real-temperature stability studies may be confined to the proposed storage temperature.

#### B. Humidity (6.2)

Biotechnological/biological products are generally distributed in containers protecting them against humidity. Therefore, where it can be demonstrated that the proposed containers (and conditions of storage) afford sufficient protection against high and low humidity, stability tests at different relative humidities can usually be omitted. Where humidity-protecting containers are not used, appropriate stability data should be provided.

#### C. Accelerated and Stress Conditions (6.3)

As previously noted, the expiration dating should be based on real-time/real-temperature data. However, it is strongly suggested that studies be conducted on the drug substance and drug product under accelerated and stress conditions. Studies under accelerated conditions may provide useful support data for establishing the expiration date, provide product stability information or future product development (e.g., preliminary assessment of proposed manufacturing changes such as change in formulation, scale-up), assist in validation of analytical methods for the stability program, or generate information that may help elucidate the degradation profile of the drug substance or drug product. Studies under stress conditions may be useful in determining whether accidental exposures to conditions other than those proposed (e.g., during transportation) are deleterious to the product and also for evaluating which specific test parameters may be the best indicators of product stability. Studies of the exposure of the drug substance or drug product to extreme conditions may help to reveal patterns of degradation; if so, such changes should be monitored under proposed storage conditions. Although the tripartite guideline on stability describes the conditions of the accelerated and stress study, the applicant should note that those conditions may not be appropriate for biotechnological/biological products. Conditions should be carefully selected on a case-by-case basis.

#### D. Light (6.4)

Applicants should consult the appropriate regulatory authorities on a case-by-case basis to determine guidance for testing.

#### E. Container/Closure (6.5)

Changes in the quality of the product may occur due to the interactions between the formulated biotechnological/biological product and container/closure. Where the lack of interactions cannot be excluded in liquid products (other than sealed ampules), stability studies should include samples maintained in the inverted or horizontal position (i.e., in contact with the closure), as well as in the upright position, to determine the effects of the closure on product quality. Data should be supplied for all different container/closure combinations that will be marketed.

In addition to the standard data necessary for a conventional single-use vial, the applicant should demonstrate that the closure used with a multiple-dose vial is capable of withstanding the conditions of repeated insertions and withdrawals so that the product retains its full potency, purity, and quality for the maximum period specified in the instructions-for-use on containers, packages, and/or package inserts. Such labeling should be in accordance with relevant national/regional requirements.

#### F. Stability after Reconstitution of Freeze-Dried Product (6.6)

The stability of freeze-dried products after their reconstitution should be demonstrated for the conditions and the maximum storage period specified on containers, packages, and/or package inserts. Such labeling should be in accordance with relevant national/regional requirements.

### VII. TESTING FREQUENCY (7)

The shelf lives of biotechnological/biological products may vary from days to several years. Thus, it is difficult to draft uniform guidelines regarding the stability study duration and testing frequency that would be applicable to all types of biotechnological/biological products. With only a few exceptions, however, the shelf lives for existing products and potential future products will be within the range of 0.5 to 5 years. Therefore, the guidance is based upon expected shelf lives in that range. This takes into account the fact that degradation of biotechnological/biological products may not be governed by the same factors during different intervals of a long storage period.

When shelf lives of 1 year or less are proposed, the real-time stability studies should be conducted monthly for the first 3 months and at 3 month intervals thereafter. For products with proposed shelf lives of greater than 1 year, the studies should be conducted every 3 months during the first year of storage, every 6 months during the second year, and annually thereafter.

While the testing intervals listed above may be appropriate in the preapproval or prelicense stage, reduced testing may be appropriate after approval or licensure where data are available that demonstrate adequate stability. Where data exist that indicate the stability of a product is not compromised, the applicant is encouraged to submit a protocol that supports elimination of specific test intervals (e.g., 9-month testing) for postapproval/postlicensure, long-term studies.

#### VIII. SPECIFICATIONS (8)

Although biotechnological/biological products may be subject to significant losses of activity, physicochemical changes, or degradation during storage, international and national regulations have provided little guidance with respect to distinct release and end of shelf life specifications. Recommendations for maximum acceptable losses of activity, limits for physicochemical changes, or degradation during the proposed shelf life have not been developed for individual types or groups of biotechnological/biological products but are considered on a case-by-case basis. Each product should retain its specifications within established limits for safety, purity, and potency throughout its proposed shelf life. These specifications and limits should be derived from all available information using the appropriate statistical methods. The use of different specifications for release and expiration should be supported by sufficient data to demonstrate that the clinical performance is not affected, as discussed in the tripartite guideline on stability.

#### IX. LABELING (9)

For most biotechnological/biological drug substances and drug products, precisely defined storage temperatures are recommended. Specific recommendations should be stated, particularly for drug substances and drug products that cannot tolerate freezing. These conditions, and where appropriate, recommendations for protection against light and/or humidity, should appear on containers, packages, and/or package inserts. Such labeling should be in accordance with relevant national and regional requirements.

#### X. GLOSSARY (10)

- **Conjugated Product**—A conjugated product is made up of an active ingredient (e.g., peptide, carbohydrate) bound covalently or noncovalently to a carrier (e.g., protein, peptide, inorganic mineral) with the objective of improving the efficacy or stability of the product.
- **Degradation Product**—A molecule resulting from a change in the drug substance (bulk material) brought about over time. For the purpose of stability testing of the products described in this guideline, such changes could occur as a result of processing or storage (e.g., by deamidation, oxidation, aggregation, proteolysis). For biotechnological/biological products, some degradation products may be active.
- **Impurity**—Any component of the drug substance (bulk material) or drug product (final container product) that is not the chemical entity defined as the drug substance, an excipient, or other additives to the drug product.
- **Intermediate**—For biotechnological/biological products, a material produced during a manufacturing process that is not the drug substance or the drug product but for which manufacture is critical to the successful production of the drug substance or the drug product. Generally, an intermediate will be quantifiable and specifications will be established to determine the successful completion of the manufacturing step before continuation of the manufacturing process. This includes material that may undergo further molecular modification or be held for an extended period before further processing.
- **Manufacturing Scale Production**—Manufacture at the scale typically encountered in a facility intended for product production for marketing.
- **Pilot-Plant Scale**—The production of the drug substance or drug product by a procedure fully representative of and simulating that to be applied at manufacturing scale. The methods of cell expansion, harvest, and product purification should be identical except for the scale of production.

1 This guideline was developed within the Expert Working Group (Quality) of the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) and has been subject to consultation by the regulatory parties, in accordance with the ICH process. This document has been endorsed by the ICH Steering Committee at Step 4 of the ICH process, November 20, 1995. At Step 4 of the process, the final draft is recommended for adoption to the regulatory bodies of the European Union, Japan and the USA. This guideline was published in the Federal Register on July 10, 1996 (61 FR 36466) and is applicable to drug and biological products. Although this guideline does not create or confer any rights for or on any person and does not operate to bind FDA or the industry, it does represent the agency's current thinking on stability testing of biotechnological/biological products. For additional copies of this guideline, contact the Drug Information Branch, HFD-210, CDER, FDA, 5600 Fishers Lane, Rockville, MD 20857 (Phone: 301-827-4573) or the Manufacturers Assistance and Communication Staff (HFM-42), CBER, FDA, 1401 Rockville Pike, Rockville, MD 20852-1448. Send one self-addressed adhesive label to assist the offices in processing your request. An electronic version of this guidance is also available via Internet using the World Wide Web (WWW) (connect to the CDER Home Page at <http://www.fda.gov/cder> and go to the "Regulatory Guidance" section).

1050 VIRAL SAFETY EVALUATION OF BIOTECHNOLOGY PRODUCTS DERIVED FROM CELL LINES OF HUMAN OR ANIMAL ORIGIN

#### I. INTRODUCTION

This document is concerned with testing and evaluation of the viral safety of biotechnology products derived from characterized cell lines of human or animal origin (i.e., mammalian, avian, insect), and outlines data that should be submitted in the marketing application/registration package. For the purposes of this document, the term virus excludes nonconventional transmissible agents like those associated with Bovine Spongiform Encephalopathy (BSE) and scrapie. Applicants are encouraged to discuss issues associated with BSE with the regulatory authorities.

The scope of the document covers products derived from cell cultures initiated from characterized cell banks. It covers products derived from *in vitro* cell culture, such as interferons, monoclonal antibodies, and recombinant deoxyribonucleic acid (DNA)-derived products including recombinant subunit vaccines, and also includes products derived from hybridoma cells grown *in vivo* as ascites. In this latter case, special considerations apply and additional information on testing cells propagated *in vivo* is contained in [Appendix 1](#). Inactivated vaccines, all live vaccines containing self-replicating agents, and genetically engineered live vectors are excluded from the scope of this document.

The risk of viral contamination is a feature common to all biotechnology products derived from cell lines. Such contamination could have serious clinical consequences and can arise from the contamination of the source cell lines themselves (cell substrates) or from adventitious introduction of virus during production. To date, however, biotechnology products derived from cell lines have not been implicated in the transmission of viruses. Nevertheless, it is expected that the safety of these products with regard to viral contamination can be reasonably assured only by the application of a virus testing program and assessment of virus removal and inactivation achieved by the manufacturing process, as outlined below.

Three principal, complementary approaches have evolved to control the potential viral contamination of biotechnology products:

Selecting and testing cell lines and other raw materials, including media components, for the absence of undesirable viruses which may be infectious and/or pathogenic for humans.

(2) Assessing the capacity of the production processes to clear infectious viruses;

(3) Testing the product at appropriate steps of production for absence of contaminating infectious viruses.

All testing suffers from the inherent limitation of quantitative virus assays, i.e., that the ability to detect low viral concentrations depends for statistical reasons on the size of the sample. Therefore, no single approach will necessarily establish the safety of a product. Confidence that infectious virus is absent from the final product will in many instances not be derived solely from direct testing for their presence, but also from a demonstration that the purification regimen is capable of removing and/or inactivating the viruses.

The type and extent of viral tests and viral clearance studies needed at different steps of production will depend on various factors and should be considered on a case-by-case and step-by-step basis. The factors that should be taken into account include the extent of cell bank characterization and qualification, the nature of any viruses detected, culture medium constituents, culture methods, facility and equipment design, the results of viral tests after cell culture, the ability of the process to clear viruses, and the type of product and its intended clinical use.

The purpose of this document is to describe a general framework for virus testing, experiments for the assessment of viral clearance, and a recommended approach for the design of viral tests and viral clearance studies. Related information is described in the appendices and selected definitions are provided in the glossary.

Manufacturers should adjust the recommendations presented here to their specific product and its production process. The approach used by manufacturers in their overall strategy for ensuring viral safety should be explained and justified. In addition to the detailed data that is provided, an overall summary of the viral safety assessment would be useful in facilitating the review by regulatory authorities. This summary should contain a brief description of all aspects of the viral safety studies and strategies used to prevent virus contamination as they pertain to this document.

## II. POTENTIAL SOURCES OF VIRUS CONTAMINATION

Viral contamination of biotechnology products may arise from the original source of the cell lines or from adventitious introduction of virus during production processes.

### A. Viruses That Could Occur in the Master Cell Bank (MCB)

Cells may have latent or persistent virus infection (e.g., herpesvirus) or endogenous retrovirus which may be transmitted vertically from one cell generation to the next, since the viral genome persists within the cell. Such viruses may be constitutively expressed or may unexpectedly become expressed as an infectious virus. Viruses can be introduced into the MCB by several routes such as: (1) Derivation of cell lines from infected animals; (2) use of virus to establish the cell line; (3) use of contaminated biological reagents such as animal serum components; (4) contamination during cell handling.

### B. Adventitious Viruses That Could Be Introduced During Production

Adventitious viruses can be introduced into the final product by several routes including, but not limited to, the following: (1) Use of contaminated biological reagents such as animal serum components; (2) use of a virus for the induction of expression of specific genes encoding a desired protein; (3) use of a contaminated reagent, such as a monoclonal antibody affinity column; (4) use of a contaminated excipient during formulation; and (5) contamination during cell and medium handling. Monitoring of cell culture parameters can be helpful in the early detection of potential adventitious viral contamination.

## III. CELL LINE QUALIFICATION: TESTING FOR VIRUSES

An important part of qualifying a cell line for use in the production of a biotechnology product is the appropriate testing for the presence of virus.

### A. Suggested Virus Tests for MCB, Working Cell Bank (WCB) and Cells at the Limit of In Vitro Cell Age Used for Production

[Table 1](#) shows examples of virus tests to be performed once only at various cell levels, including MCB, WCB, and cells at the limit of in vitro cell age used for production.

Table 1. Examples of Virus Tests to be Performed Once At Various Cell Levels

	MCB	WCB <sup>1</sup>	Cells at the Limit <sup>2</sup>
Tests for Retroviruses and Other Endogenous Viruses			
Infectivity	+	-	+
Electron microscopy <sup>3</sup>	+ <sup>3</sup>	-	+ <sup>3</sup>
Reverse transcriptase <sup>4</sup>	+ <sup>4</sup>	-	+ <sup>4</sup>
Other virus-specific tests <sup>5</sup>	as appropriate <sup>5</sup>	-	as appropriate <sup>5</sup>
Tests for Nonendogenous or Adventitious Viruses			
In vitro Asays	+	- <sup>6</sup>	+
In vivo Assays	+	- <sup>6</sup>	+
Antibody production tests <sup>7</sup>	+ <sup>7</sup>	-	-
Other virus-specific tests <sup>8</sup>	+ <sup>8</sup>	-	-

1. See text—section III.A.2.

2. Cells at the limit: Cells at the limit of in vitro cell age used for production (See text—section III.A.3.).

3. May also detect other agents.

4. Not necessary if positive by retrovirus infectivity test.

5. As appropriate for cell lines which are known to have been infected by such agents.

6. For the first WCB, this test should be performed on cells at the limit of in vitro cell age, generated from that WCB; for WCB's subsequent to the first WCB, a single in vitro and in vivo test can be done either directly on the WCB or on cells at the limit of in vitro cell age.

7. e.g., MAP, RAP, HAP—usually applicable for rodent cell lines.

8. e.g., tests for cell lines derived from human, nonhuman primate, or other cell lines as appropriate.

### 1. Master Cell Bank

Extensive screening for both endogenous and nonendogenous viral contamination should be performed on the MCB. For heterohybrid cell lines in which one or more partners are human or nonhuman primate in origin, tests should be performed in order to detect viruses of human or nonhuman primate origin because viral contamination arising from these cells may pose a particular hazard.

Testing for nonendogenous viruses should include in vitro and in vivo inoculation tests and any other specific tests, including species-specific tests such as the mouse antibody production (MAP) test, that are appropriate, based on the passage history of the cell line, to detect possible contaminating viruses.

### 2. Working Cell Bank

Each WCB as a starting cell substrate for drug production should be tested for adventitious virus either by direct testing or by analysis of cells at the limit of in vitro cell age, initiated from the WCB. When appropriate nonendogenous virus tests have been performed on the MCB and cells cultured up to or beyond the limit of in vitro cell age have been derived from the WCB and used for testing for the presence of adventitious viruses, similar tests need not be performed on the initial WCB. Antibody production tests are usually not necessary for the WCB. An alternative approach in which full tests are carried out on the WCB rather than on the MCB would also be considered acceptable.

### 3. Cells at the Limit of In Vitro Cell Age Used for Production

The limit of in vitro cell age used for production should be based on data derived from production cells expanded under pilot-plant scale or commercial-scale conditions to the proposed in vitro cell age or beyond. Generally, the production cells are obtained by expansion of the WCB; the MCB could also be used to prepare the production cells. Cells at the limit of in vitro cell age should be evaluated once for those endogenous viruses that may have been undetected in the MCB and WCB. The performance of suitable tests (e.g., in vitro and in vivo) at least once on cells at the limit of in vitro cell age used for production would provide further assurance that the production process is not prone to contamination by adventitious virus. If any adventitious viruses are detected at this level, the process should be carefully checked in order to determine the cause of the contamination, and should be completely redesigned if necessary.

### B. Recommended Viral Detection and Identification Assays

Numerous assays can be used for the detection of endogenous and adventitious viruses. [Table 2](#) outlines examples for these assays. They should be regarded as assay protocols recommended for the present, but the list is not all-inclusive or definitive. Since the most appropriate techniques may change with scientific progress, proposals for alternative techniques, when accompanied by adequate supporting data, may be acceptable. Manufacturers are encouraged to discuss these alternatives with the regulatory authorities. Other tests may be necessary depending on the individual case. Assays should include appropriate controls to ensure adequate sensitivity and specificity. Wherever a relatively high possibility of the presence of a specific virus can be predicted from the species of origin of the cell substrate, specific tests and/or approaches may be necessary. If the cell line used for production is of human or nonhuman primate origin, additional tests for human viruses, such as those causing immunodeficiency diseases and hepatitis, should be performed unless otherwise justified. The polymerase chain reaction (PCR) may be appropriate for detection of sequences of other human viruses as well as for other specific viruses. The following is a brief description of a general framework and philosophical background within which the manufacturer should justify what was done.

Table 2. Examples of the Use and Limitations of Assays Which May be Used to Test for Virus

Test	Test Article	Detection Capability	Detection Limitation
Antibody production	Lysate of cells and their culture medium	Specific viral antigens	Antigens not infectious for animal test system
in vivo virus screen	Lysate of cells and their culture medium	Broad range of viruses pathogenic for humans	Agents failing to replicate or produce diseases in the test system
in vitro virus screen for:		Broad range of viruses pathogenic for humans	Agents failing to replicate or produce diseases in the test system
1. Cell bank characterization	1. Lysate of cells and their culture medium (for co-cultivation, intact cells should be in the test article)		
2. Production screen	2. Unprocessed bulk harvest or lysate of cells and their cell culture medium from the production reactor		
TEM on:		Virus and virus-like particles	Qualitative assay with assessment of identity
1. Cell substrate	1. Viable cells		
2. Cell culture supernatant	2. Cell-free culture supernatant		
Reverse transcriptase (RT)	Cell-free culture supernatant	Retroviruses and expressed retroviral RT	Only detects enzymes with optimal activity under preferred conditions. Interpretation may be difficult due to presence of cellular enzymes; background with some concentrated samples
Retrovirus (RV) infectivity	Cell-free culture supernatant	Infectious retroviruses	RV failing to replicate or form discrete foci or plaques in the chosen test system
Cocultivation	Viable cells	Infectious retroviruses	RV failing to replicate
1. Infectivity endpoint			1. See above under RV infectivity
2. TEM endpoint			2. See above under TEM <sup>1</sup>
3. RT endpoint			3. See above under RT
PCR (Polymerase chain reaction)	Cells, culture fluid and other materials	Specific virus sequences	Primer sequences must be present. Does not indicate whether virus is infectious.

1 In addition, difficult to distinguish test article from indicator cells.

#### 1. Tests for Retroviruses

For the MCB and for cells cultured up to or beyond the limit of in vitro cell age used for production, tests for retroviruses, including infectivity assays in sensitive cell cultures and electron microscopy (EM) studies, should be carried out. If infectivity is not detected and no retrovirus or retrovirus-like particles have been observed by EM, reverse transcriptase (RT) or other appropriate assays should be performed to detect retroviruses that may be noninfectious. Induction studies have not been found to be useful.

#### 2. In Vitro Assays

In vitro tests are carried out by the inoculation of a test article (see [Table 2](#)) into various susceptible indicator cell cultures capable of detecting a wide range of human and relevant animal viruses. The choice of cells used in the test is governed by the species of origin of the cell bank to be tested, but should include a human and/or a nonhuman primate cell line susceptible to human viruses. The nature of the assay and the sample to be tested are governed by the type of virus which may possibly be present based on the origin or handling of the cells. Both cytopathic and hemadsorbing viruses should be sought.

#### 3. In Vivo Assays

A test article (see [Table 2](#)) should be inoculated into animals, including suckling and adult mice, and in embryonated eggs to reveal viruses that cannot grow in cell cultures. Additional animal species may be used, depending on the nature and source of the cell lines being tested. The health of the animals should be monitored and any abnormality should be investigated to establish the cause of the illness.

#### 4. Antibody Production Tests

Species-specific viruses present in rodent cell lines may be detected by inoculating test article (see [Table 2](#)) into virus-free animals and examining the serum antibody level or enzyme activity after a specified period. Examples of such tests are the mouse antibody production (MAP) test, rat antibody production (RAP) test, and hamster antibody production (HAP) test.

The viruses currently screened for in the antibody production assays are discussed in [Table 3](#).

Table 3. Virus Detected in Antibody Production Tests

AP	HAP	RAP
Ectromelia Virus <sup>2,3</sup>	Lymphocytic Choriomeningitis Virus (LCM) <sup>1,3</sup>	Hantaan Virus <sup>1,3</sup>
Hantaan Virus <sup>1,3</sup>	Pneumonia Virus of Mice (PVM) <sup>2,3</sup>	Kilham Rat Virus (KRV) <sup>2,3</sup>
K Virus <sup>2</sup>	Reovirus Type 3 (Reo3) <sup>1,3</sup>	Mouse Encephalomyelitis Virus (Theilers, GDVII) <sup>2</sup>
Lactic Dehydrogenase Virus (LDM) <sup>1,3</sup>	Sendai Virus <sup>1,3</sup>	Pneumonia Virus of Mice (PVM) <sup>2,3</sup>
Lymphocytic Choriomeningitis Virus (LCM) <sup>1,3</sup>	SV5	Rat Coronavirus (RCV) <sup>2</sup>
Minute Virus of Mice <sup>2,3</sup>		Reovirus Type 3 (Reo3) <sup>1,3</sup>
Mouse Adenovirus (MAV) <sup>2,3</sup>		Sendai Virus <sup>1,3</sup>
Mouse Cytomegalovirus (MCMV) <sup>2,3</sup>		Slalocryoadenitis Virus (SDAV) <sup>2</sup>
Mouse Encephalomyelitis Virus (Theilers, GDVII) <sup>2</sup>		Toolan Virus (HI) <sup>2,3</sup>
Mouse Hepatitis Virus (MHV) <sup>2</sup>		
Mouse Rotavirus (EDIM) <sup>2,3</sup>		
Pneumonia Virus of Mice (PVM) <sup>2,3</sup>		
Polyoma Virus <sup>2</sup>		
Reovirus Type 3 (Reo3) <sup>1,3</sup>		
Sendai Virus <sup>1,3</sup>		
Thymic Virus <sup>2</sup>		

1. Viruses for which there is evidence of capacity for infecting humans or primates.

2. Viruses for which there is no evidence of capacity for infecting humans.

3. Virus capable of replicating in vitro in cells of human or primate origin.

#### C. Acceptability of Cell Lines

It is recognized that some cell lines used for the manufacture of product will contain endogenous retroviruses, other viruses, or viral sequences. In such circumstances, the action plan recommended for manufacture is described in section V. of this document. The acceptability of cell lines containing viruses other than endogenous retroviruses will be considered on an individual basis by the regulatory authorities, by taking into account a risk/benefit analysis based on the benefit of the product and its intended clinical use, the nature of the contaminating viruses, their potential for infecting humans or for causing disease in humans, the purification process for the product (e.g., viral clearance evaluation data), and the extent of the virus tests conducted on the purified bulk.

#### IV. TESTING FOR VIRUSES IN UNPROCESSED BULK

The unprocessed bulk constitutes one or multiple pooled harvests of cells and culture media. When cells are not readily accessible (e.g., hollow fiber or similar systems), the unprocessed bulk would constitute fluids harvested from the fermenter. A representative sample of the unprocessed bulk, removed from the production reactor prior to further processing, represents one of the most suitable levels at which the possibility of adventitious virus contamination can be determined with a high probability of detection. Appropriate testing for viruses should be performed at the unprocessed bulk level unless virus testing is made more sensitive by initial partial processing (e.g., unprocessed bulk may be toxic in test cell cultures, whereas partially processed bulk may not be toxic).

In certain instances, it may be more appropriate to test a mixture consisting of both intact and disrupted cells and their cell culture supernatants removed from the production reactor prior to further processing. Data from at least three lots of unprocessed bulk at pilot-plant scale or commercial scale should be submitted as part of the marketing application/registration package.

It is recommended that manufacturers develop programs for the ongoing assessment of adventitious viruses in production batches. The scope, extent, and frequency of virus testing on the unprocessed bulk should be determined by taking several points into consideration, including the nature of the cell lines used to produce the desired products, the results and extent of virus tests performed during the qualification of the cell lines, the cultivation method, raw material sources, and results of viral clearance studies. In vitro screening tests, using one or several cell lines, are generally employed to test unprocessed bulk. If appropriate, a PCR test or other suitable methods may be used.

Generally, harvest material in which adventitious virus has been detected should not be used to manufacture the product. If any adventitious viruses are detected at this level, the process should be carefully checked to determine the cause of the contamination, and appropriate actions taken.

#### V. RATIONALE AND ACTION PLAN FOR VIRAL CLEARANCE STUDIES AND VIRUS TESTS ON PURIFIED BULK

It is important to design the most relevant and rational protocol for virus tests from the MCB level, through the various steps of drug production, to the final product including evaluation and characterization of viral clearance from unprocessed bulk. The evaluation and characterization of viral clearance plays a critical role in this scheme. The goal should be to obtain the best reasonable assurance that the product is free of virus contamination.

In selecting viruses to use for a clearance study, it is useful to distinguish between the need to evaluate processes for their ability to clear viruses that are known to be present and the desire to estimate the robustness of the process by characterizing the clearance of nonspecific "model" viruses (described later). Definitions of "relevant," specific, and nonspecific "model" viruses are given in the glossary. Process evaluation requires knowledge of how much virus may be present in the process, such as the unprocessed bulk, and how much can be cleared in order to assess product safety. Knowledge of the time dependence for inactivation procedures is helpful in assuring the effectiveness of the inactivation process. When evaluating clearance of known contaminants, in-depth, time-dependent inactivation studies, demonstration of reproducibility of inactivation/removal, and evaluation of process parameters should be provided. When a manufacturing process is characterized for robustness of clearance using nonspecific "model" viruses, particular attention should be paid to nonenveloped viruses in the study design. The extent of viral clearance characterization studies may be influenced by the results of tests on cell lines and unprocessed bulk. These studies should be performed as described in section VI. below.

**Table 4** presents an example of an action plan in terms of process evaluation and characterization of viral clearance as well as virus tests on purified bulk, in response to the results of virus tests on cells and/or the unprocessed bulk. Various cases are considered. In all cases, characterization of clearance using nonspecific "model" viruses should be performed. The most common situations are Cases A and B. Production systems contaminated with a virus other than a rodent retrovirus are normally not used. Where there are convincing and well justified reasons for drug production using a cell line from Cases C, D, or E, these should be discussed with the regulatory authorities. With Cases C, D, and E, it is important to have validated effective steps to inactivate/remove the virus in question from the manufacturing process.

Table 4. Action Plan for Process Assessment of Viral Clearance and Virus Tests on Purified Bulk

	Case A	Case B	Case C <sup>2</sup>	Case D <sup>2</sup>	Case E <sup>2</sup>
Status					
Presence of virus <sup>1</sup>	—	—	+	+	(+) <sup>3</sup>
Virus-like particles <sup>1</sup>	—	—	—	—	(+) <sup>3</sup>
Retrovirus-like particles <sup>1</sup>	—	+	—	—	(+) <sup>3</sup>
Virus identified	not applicable	+	+	+	—

Action	not applicable	- <sup>4</sup>	- <sup>4</sup>	+	unknown
Process characterization of viral clearance using nonspecific "model" viruses	yes <sup>5</sup>	yes <sup>5</sup>	yes <sup>5</sup>	yes <sup>5</sup>	yes <sup>7</sup>
Process evaluation of viral clearance using "relevant" or specific "model" viruses	no	yes <sup>6</sup>	yes <sup>6</sup>	yes <sup>6</sup>	yes <sup>7</sup>
Test for virus in purified bulk	not applicable	yes <sup>8</sup>	yes <sup>8</sup>	yes <sup>8</sup>	yes <sup>8</sup>

1 Results of virus tests for the cell substrate and/or at the unprocessed bulk level. Cell cultures used for production which are contaminated with viruses will generally not be acceptable. Endogenous viruses (such as retroviruses) or viruses that are an integral part of the MCB may be acceptable if appropriate viral clearance evaluation procedures are followed.

2 The use of source material which is contaminated with viruses, whether or not they are known to be infectious and/or pathogenic in humans, will only be acceptable under very exceptional circumstances.

3 Virus has been observed by either direct or indirect methods.

4 Believed to be nonpathogenic.

5 Characterization of clearance using nonspecific "model" viruses should be performed.

6 Process evaluation for "relevant" viruses or specific "model" viruses should be performed.

7 See text under Case E.

8 The absence of detectable virus should be confirmed for purified bulk by means of suitable methods having high specificity and sensitivity for the detection of the virus in question. For the purpose of marketing authorization, data from at least 3 lots of purified bulk manufactured at pilot-plant or commercial scale should be provided. However for cell lines such as CHO cells for which the endogenous particles have been extensively characterized and adequate clearance has been demonstrated, it is not usually necessary to assay for the presence of the noninfectious particles in purified bulk.

Case A: Where no virus, virus-like particle, or retrovirus-like particle has been demonstrated in the cells or in the unprocessed bulk, virus removal and inactivation studies should be performed with nonspecific "model" viruses as previously stated.

Case B: Where only a rodent retrovirus (or a retrovirus-like particle that is believed to be nonpathogenic, such as rodent A- and R-type particles) is present, process evaluation using a specific "model" virus, such as a murine leukemia virus, should be performed. Purified bulk should be tested using suitable methods having high specificity and sensitivity for the detection of the virus in question. For marketing authorization, data from at least three lots of purified bulk at pilot-plant scale or commercial scale should be provided. Cell lines such as Chinese hamster ovary (CHO), C127, baby hamster kidney (BHK), and murine hybridoma cell lines have frequently been used as substrates for drug production with no reported safety problems related to viral contamination of the products. For these cell lines in which the endogenous particles have been extensively characterized and clearance has been demonstrated, it is not usually necessary to assay for the presence of the noninfectious particles in purified bulk. Studies with nonspecific "model" viruses, as in Case A, are appropriate.

Case C: When the cells or unprocessed bulk are known to contain a virus, other than a rodent retrovirus, for which there is no evidence of capacity for infecting humans (such as those identified by footnote 2 in [Table 3](#), except rodent retroviruses (Case B)), virus removal and inactivation evaluation studies should use the identified virus. If it is not possible to use the identified virus, "relevant" or specific "model" viruses should be used to demonstrate acceptable clearance. Time-dependent inactivation for identified (or "relevant" or specific "model") viruses at the critical inactivation step(s) should be obtained as part of process evaluation for these viruses. Purified bulk should be tested using suitable methods having high specificity and sensitivity for the detection of the virus in question. For the purpose of marketing authorization, data from at least three lots of purified bulk manufactured at pilot-plant scale or commercial scale should be provided.

Case D: Where a known human pathogen, such as those indicated by footnote 1 in [Table 3](#), is identified, the product may be acceptable only under exceptional circumstances. In this instance, it is recommended that the identified virus be used for virus removal and inactivation evaluation studies and specific methods with high specificity and sensitivity for the detection of the virus in question be employed. If it is not possible to use the identified virus, "relevant" and/or specific "model" viruses (described later) should be used. The process should be shown to achieve the removal and inactivation of the selected viruses during the purification and inactivation processes. Time-dependent inactivation data for the critical inactivation step(s) should be obtained as part of process evaluation. Purified bulk should be tested using suitable methods having high specificity and sensitivity for the detection of the virus in question. For the purpose of marketing authorization, data from at least three lots of purified bulk manufactured at pilot-plant scale or commercial scale should be provided.

Case E: When a virus that cannot be classified by currently available methodologies is detected in the cells or unprocessed bulk, the product is usually considered unacceptable since the virus may prove to be pathogenic. In the very rare case where there are convincing and well justified reasons for drug production using such a cell line, this should be discussed with the regulatory authorities before proceeding further.

## VI. EVALUATION AND CHARACTERIZATION OF VIRAL CLEARANCE PROCEDURES

Evaluation and characterization of due virus removal and/or inactivation procedures play an important role in establishing the safety of biotechnology products. Many instances of contamination in the past have occurred with agents whose presence was not known or even suspected, and though this happened to biological products derived from various source materials other than fully characterized cell lines, assessment of viral clearance will provide a measure of confidence that any unknown, unsuspected, and harmful viruses may be removed. Studies should be carried out in a manner that is well documented and controlled.

The objective of viral clearance studies is to assess process step(s) that can be considered to be effective in inactivating/removing viruses and to estimate quantitatively the overall level of virus reduction obtained by the process. This should be achieved by the deliberate addition ("spiking") of significant amounts of a virus to the crude material and/or to different fractions obtained during the various process steps and demonstrating its removal or inactivation during the subsequent steps. It is not considered necessary to evaluate or characterize every step of a manufacturing process if adequate clearance is demonstrated by the use of fewer steps. It should be borne in mind that other steps in the process may have an indirect effect on the viral inactivation/removal achieved. Manufacturers should explain and justify the approach used in studies for evaluating virus clearance.

The reduction of virus infectivity may be achieved by removal of virus particles or by inactivation of viral infectivity. For each production step assessed, the possible mechanism of loss of viral infectivity should be described with regard to whether it is due to inactivation or removal. For inactivation steps, the study should be planned in such a way that samples are taken at different times and an inactivation curve constructed (see section VI.B.5.).

Viral clearance evaluation studies are performed to demonstrate the clearance of a virus known to be present in the MCB and/or to provide some level of assurance that adventitious viruses which could not be detected, or might gain access to the production process, would be cleared. Reduction factors are normally expressed on a logarithmic scale, which implies that, while residual virus infectivity will never be reduced to zero, it may be greatly reduced mathematically.

In addition to clearance studies for viruses known to be present, studies to characterize the ability to remove and/or inactivate other viruses should be conducted. The purpose of studies with viruses exhibiting a range of biochemical and biophysical properties that are not known or expected to be present is to characterize the robustness of the procedure rather than to achieve a specific inactivation or removal goal. A demonstration of the capacity of the production process to inactivate or remove viruses is desirable (see section VI.C.). Such studies are not performed to evaluate a specific safety risk. Therefore, a specific clearance value need not be achieved.

### A. The Choice of Viruses for the Evaluation and Characterization of Viral Clearance

Viruses for clearance evaluation and process characterization studies should be chosen to resemble viruses which may contaminate the product and to represent a wide range of physico-chemical properties in order to test the ability of the system to eliminate viruses in general. The manufacturer should justify the choice of viruses in accordance with the aims of the evaluation and characterization study and the guidance provided in this document.

#### 1. "Relevant" Viruses and "Model" Viruses

A major issue in performing a viral clearance study is to determine which viruses should be used. Such viruses fall into three categories: "Relevant" viruses, specific "model" viruses, and nonspecific "model" viruses.

"Relevant" viruses are viruses used in process evaluation of viral clearance studies which are either the identified viruses, or of the same species as the viruses that are known, or likely to contaminate the cell substrate or any other reagents or materials used in the production process. The purification and/or inactivation process should demonstrate the capability to remove and/or inactivate such viruses. When a "relevant" virus is not available or when it is not well adapted to process evaluation of viral clearance studies (e.g., it cannot be grown *in vitro* to sufficiently high titers), a specific "model" virus should be used as a substitute. An appropriate specific "model" virus may be a virus which is closely related to the known or suspected virus (same genus or family), having similar physical and chemical properties to the observed or suspected virus.

Cell lines derived from rodents usually contain endogenous retrovirus particles or retrovirus-like particles, which may be infectious (C-type particles) or noninfectious (cytoplasmic A- and R-type particles). The capacity of the manufacturing process to remove and/or inactivate rodent retroviruses from products obtained from such cells should be determined. This may be accomplished by using a murine leukemia virus, a specific "model" virus in the case of cells of murine origin. When human cell lines secreting monoclonal antibodies have been obtained by the immortalization of B lymphocytes by Epstein-Barr Virus (EBV), the ability of the manufacturing process to remove and/or inactivate a herpes virus should be determined. Pseudorabies virus may also be used as a specific "model" virus.

When the purpose is to characterize the capacity of the manufacturing process to remove and/or inactivate viruses in general, i.e., to characterize the robustness of the clearance process, viral clearance characterization studies should be performed with nonspecific "model" viruses with differing properties. Data obtained from studies with "relevant" and/or specific "model" viruses may also contribute to this assessment. It is not necessary to test all types of viruses. Preference should be given to viruses that display a significant resistance to physical and/or chemical treatments. The results obtained for such viruses provide useful information about the ability of the production process to remove and/or inactivate viruses in general. The choice and number of viruses used will be influenced by the quality and characterization of the cell lines and the production process.

Examples of useful "model" viruses representing a range of physico-chemical structures and examples of viruses which have been used in viral clearance studies are given in Appendix 2 and [Table A-1](#).

Table A-1. Examples of Viruses Which Have Been Used in Viral Clearance Studies

Virus	Family	Genus	Natural Host	Genome	Env	Size (nm)	Shape	Resistance <sup>1</sup>
Vesicular Stomatitis Virus	Rhabdo	Vesiculo-virus	Equine Bovine	RNA	yes	70 × 150	Bullet	Low
Parainfluenza Virus	Paramyxo	Paramyxo-virus	Various	RNA	yes	100–200	Pleo/Spher	Low
MuLV	Retro	Type C oncovirus	Mouse	RNA	yes	80–110	Spherical	Low
Sindbis Virus	Toga	Alphavirus	Human	RNA	yes	60–70	Spherical	Low
BVDV	Flavi	Pestivirus	Bovine	RNA	yes	50–70	Pleo/Spher	Low
Pseudo-rabies Virus	Herpes		Swine	DNA	yes	120–200	Spherical	Med
Poliovirus Sabin Type 1	Picorna	Enterovirus	Human	RNA	no	25–30	Icosahedral	Med

1 Resistance to physico-chemical treatments based on studies of production processes. Resistance is relative to the specific treatment and it is used in the context of the understanding of the biology of the virus and the nature of the manufacturing process. Actual results will vary according to the treatment. These viruses are examples only and their use is not considered mandatory.

## 2. Other Considerations

Additional points to be considered are as follows:

(a) Viruses which can be grown to high titer are desirable, although this may not always be possible.

(b) There should be an efficient and reliable assay for the detection of each virus used, for every stage of manufacturing that is tested.

(c) Consideration should be given to the health hazard which certain viruses may pose to the personnel performing the clearance studies.

## B. Design and Implications of Viral Clearance Evaluation and Characterization Studies

### 1. Facility and Staff

It is inappropriate to introduce any virus into a production facility because of good manufacturing practice (GMP) constraints. Therefore, viral clearance studies should be conducted in a separate laboratory equipped for virological work and performed by staff with virological expertise in conjunction with production personnel involved in designing and preparing a scaled-down version of the purification process.

### 2. Scaled-down Production System

The validity of the scaling down should be demonstrated. The level of purification of the scaled-down version should represent as closely as possible the production procedure. For chromatographic equipment, column bed-height, linear flow-rate, flow-rate-to-bed-volume ratio (i.e., contact time), buffer and gel types, pH, temperature, and concentration of protein, salt, and product should all be shown to be representative of commercial-scale manufacturing. A similar elution profile should result. For other procedures, similar considerations apply.

Deviations that cannot be avoided should be discussed with regard to their influence on the results.

### 3. Analysis of Step-wise Elimination of Virus

When viral clearance studies are being performed, it is desirable to assess the contribution of more than one production step to virus elimination. Steps which are likely to clear virus should be individually assessed for their ability to remove and inactivate virus and careful consideration should be given to the exact definition of an individual step. Sufficient virus should be present in the material of each step to be tested so that an adequate assessment of the effectiveness of each step is obtained. Generally, virus should be added to in-process material of each step to be tested. In some cases, simply adding high titer virus to unpurified bulk and testing its concentration between steps will be sufficient. Where virus removal results from separation procedures, it is recommended that, if appropriate and if possible, the distribution of the virus load in the different fractions be investigated. When virucidal buffers are used in multiple steps within the manufacturing process, alternative strategies such as parallel spiking in less virucidal buffers may be carried out as part of the overall process assessment. The virus titer before and after each step being tested should be determined. Quantitative infectivity assays should have adequate sensitivity and reproducibility and should be performed with sufficient replicates to ensure adequate statistical validity of the result. Quantitative assays not associated with infectivity may be used if justified. Appropriate virus controls should be included in all infectivity assays to ensure the sensitivity of the method. Also, the statistics of sampling virus when at low concentrations should be considered ([Appendix 3](#)).

### 4. Determining Physical Removal Versus Inactivation

Reduction in virus infectivity may be achieved by the removal or inactivation of virus. For each production step assessed, the possible mechanism of loss of viral infectivity should be described with regard to whether it is due to inactivation or removal. If little clearance of infectivity is achieved by the production process, and the clearance of virus is considered to be a major factor in the safety of the product, specific or additional inactivation/removal steps should be introduced. It may be necessary to distinguish between removal and inactivation

... a particular step, for example, when there is a possibility that a buffer used in more than one clearance step may contribute to inactivation during each step, i.e., the contribution of inactivation by a buffer shared by several chromatographic steps and the removal achieved by each of these chromatographic steps should be distinguished.

#### 5. Inactivation Assessment

For assessment of viral inactivation, unprocessed crude material or intermediate material should be spiked with infectious virus and the reduction factor calculated. It should be recognized that virus inactivation is not a simple, first order reaction and is usually more complex, with a fast "phase 1" and a slow "phase 2." The study should, therefore, be planned in such a way that samples are taken at different times and an inactivation curve constructed. It is recommended that studies for inactivation include at least one time point less than the minimum exposure time and greater than zero, in addition to the minimum exposure time. Additional data are particularly important where the virus is a "relevant" virus known to be a human pathogen and an effective inactivation process is being designed. However, for inactivation studies in which nonspecific "model" viruses are used or when specific "model"

viruses are used as surrogates for virus particles, such as the CHO intracytoplasmic retrovirus-like particles, reproducible clearance should be demonstrated in at least two independent studies. Whenever possible, the initial virus load should be determined from the virus that can be detected in the spiked starting material. If this is not possible, the initial virus load may be calculated from the titer of the spiking virus preparation. Where inactivation is too rapid to plot an inactivation curve using process conditions, appropriate controls should be performed to demonstrate that infectivity is indeed lost by inactivation.

#### 6. Function and Regeneration of Columns

Over time and after repeated use, the ability of chromatography columns and other devices used in the purification scheme to clear virus may vary. Some estimate of the stability of the viral clearance after several uses may provide support for repeated use of such columns. Assurance should be provided that any virus potentially retained by the production system would be adequately destroyed or removed prior to reuse of the system. For example, such evidence may be provided by demonstrating that the cleaning and regeneration procedures do not inactivate or remove virus.

#### 7. Specific Precautions

(a) Care should be taken in preparing the high-titer virus to avoid aggregation which may enhance physical removal and decrease inactivation, thus distorting the correlation with actual production.

(b) Consideration should be given to the minimum quantity of virus which can be reliably assayed.

(c) The study should include parallel control assays to assess the loss of infectivity of the virus due to such reasons as the dilution, concentration, filtration or storage of samples before titration.

(d) The virus "spike" should be added to the product in a small volume so as not to dilute or change the characteristics of the product. Diluted, test-protein sample is no longer identical to the product obtained at commercial scale.

(e) Small differences in, for example, buffers, media, or reagents can substantially affect viral clearance.

(f) Virus inactivation is time-dependent; therefore, the amount of time a spiked product remains in a particular buffer solution or on a particular chromatography column should reflect the conditions of the commercial-scale process.

(g) Buffers and product should be evaluated independently for toxicity or interference in assays used to determine the virus titer, as these components may adversely affect the indicator cells. If the solutions are toxic to the indicator cells, dilution, adjustment of the pH, or dialysis of the buffer containing spiked virus might be necessary. If the product itself has anti-viral activity, the clearance study may need to be performed without the product in a "mock" run, although omitting the product or substituting a similar protein that does not have anti-viral activity could affect the behavior of the virus in some production steps. Sufficient controls to demonstrate the effect of procedures used solely to prepare the sample for assay (e.g., dialysis, storage) on the removal/inactivation of the spiking virus should be included.

(h) Many purification schemes use the same or similar buffers or columns repetitively. The effects of this approach should be taken into account when analyzing the data. The effectiveness of virus elimination by a particular process may vary with the manufacturing stage at which it is used.

(i) Overall reduction factors may be underestimated where production conditions or buffers are too cytotoxic or virucidal and should be discussed on a case-by-case basis. Overall reduction factors may also be overestimated due to inherent limitations or inadequate design of viral clearance studies.

#### C. Interpretation of Viral Clearance Studies; Acceptability

The object of assessing virus inactivation/removal is to evaluate and characterize process steps that can be considered to be effective in inactivating/removing viruses and to estimate quantitatively the overall level of virus reduction obtained by the manufacturing process. For virus contaminants, as in Cases B through E, it is important to show that not only is the virus eliminated or inactivated, but that there is excess capacity for viral clearance built into the purification process to assure an appropriate level of safety for the final product. The amount of virus eliminated or inactivated by the production process should be compared to the amount of virus which may be present in unprocessed bulk.

To carry out this comparison, it is important to estimate the amount of virus in the unprocessed bulk. This estimate should be obtained using assays for infectivity or other methods such as transmission electron microscopy (TEM). The entire purification process should be able to eliminate substantially more virus than is estimated to be present in a single-dose-equivalent of unprocessed bulk. See [Appendix 4](#) for calculation of virus reduction factors and [Appendix 5](#) for calculation of estimated particles per dose.

Manufacturers should recognize that clearance mechanisms may differ between virus classes. A combination of factors should be considered when judging the data supporting the effectiveness of virus inactivation/removal procedures. These include:

- (i) The appropriateness of the test viruses used;
- (ii) The design of the clearance studies;
- (iii) The log reduction achieved;
- (iv) The time dependence of inactivation;
- (v) The potential effects of variation in process parameters on virus inactivation/removal;
- (vi) The limits of assay sensitivities;
- (vii) The possible selectivity of inactivation/removal procedure(s) for certain classes of viruses.

Effective clearance may be achieved by any of the following: Multiple inactivation steps, multiple complementary separation steps, or combinations of inactivation and separation steps.

Since separation methods may be dependent on the extremely specific physico-chemical properties of a virus which influence its interaction with gel matrices and precipitation properties, "model" viruses may be separated in a different manner than a target virus. Manufacturing parameters influencing separation should be properly defined and controlled. Differences may originate from changes in surface properties such as glycosylation. However, despite these potential variables, effective removal can be obtained by a combination of complementary separation steps or combinations of inactivation and separation steps. Therefore, well-designed separation steps, such as chromatographic procedures, filtration steps, and extractions, can be effective virus removal steps provided that they are performed under appropriately controlled conditions. An effective virus removal step should give a reproducible reduction of virus load shown by at least two independent studies.

An overall reduction factor is generally expressed as the sum of the individual factors. However, reduction in virus titer of the order of 1 log<sub>10</sub> or less would be considered negligible and would be ignored unless justified.

If little reduction of infectivity is achieved by the production process, and the removal of virus is considered to be a major factor in the safety of the product, a specific, additional inactivation/removal step or steps should be introduced. For all viruses, manufacturers should justify the acceptability of the reduction factors obtained. Results would be evaluated on the basis of the factors listed above.

#### D. Limitations of Viral Clearance Studies

Viral clearance studies are useful for contributing to the assurance that an acceptable level of safety in the final product is achieved but do not by themselves establish safety. However, a number of factors in the design and execution of viral clearance studies may lead to an incorrect estimate of the ability of the process to remove virus infectivity. These factors include the following:

1. Virus preparations used in clearance studies for a production process are likely to be produced in tissue culture. The behavior of a tissue culture virus in a production step may be different from that of the native virus, for example, if native and cultured viruses differ in purity or degree of aggregation.
2. Inactivation of virus infectivity frequently follows a biphasic curve in which a rapid initial phase is followed by a slower phase. It is possible that virus escaping a first inactivation step may be more resistant to subsequent steps. For example, if the resistant fraction takes the form of virus aggregates, infectivity may be resistant to a range of different chemical treatments and to heating.
3. The ability of the overall process to remove infectivity is expressed as the sum of the logarithm of the reductions at each step. The summation of the reduction factors of multiple steps, particularly of steps with little reduction (e.g., below 1 log<sub>10</sub>), may overestimate the true potential for virus elimination. Furthermore, reduction values achieved by repetition of identical or near identical procedures should not be included unless justified.
4. The expression of reduction factors as logarithmic reductions in titer implies that, while residual virus infectivity may be greatly reduced, it will never be reduced to zero. For example, a reduction in the infectivity of a preparation containing 8 log<sub>10</sub> infectious units per milliliter (mL) by a factor of 8 log<sub>10</sub> leaves zero log<sub>10</sub> per mL or one infectious unit per mL, taking into consideration the limit of detection of the assay.
5. Pilot-plant scale processing may differ from commercial-scale processing despite care taken to design the scaled-down process.
6. Addition of individual virus reduction factors resulting from similar inactivation mechanisms along the manufacturing process may overestimate overall viral clearance.

#### E. Statistics

The viral clearance studies should include the use of statistical analysis of the data to evaluate the results. The study results should be statistically valid to support the conclusions reached (see Appendix 3).

#### F. Reevaluation of Viral Clearance

Whenever significant changes in the production or purification process are made, the effect of that change, both direct and indirect, on viral clearance should be considered and the system re-evaluated as needed. For example, changes in production processes may cause significant changes in the amount of virus produced by the cell line; changes in process steps may change the extent of viral clearance.

## VII. SUMMARY

This document suggests approaches for the evaluation of the risk of viral contamination and for the removal of virus from product, thus contributing to the production of safe biotechnology products derived from animal or human cell lines, and emphasizes the value of many strategies, including:

- A. Thorough characterization/screening of cell substrate starting material in order to identify which, if any, viral contaminants are present;
- B. Assessment of risk by determination of the human tropism of the contaminants;
- C. Establishment of an appropriate program of testing for adventitious viruses in unprocessed bulk;
- D. Careful design of viral clearance studies using different methods of virus inactivation or removal in the same production process in order to achieve maximum viral clearance; and
- E. Performance of studies which assess virus inactivation and removal.

## GLOSSARY

Adventitious Virus. See Virus.

Cell Substrate. Cells used to manufacture product.

Endogenous Virus. See Virus.

Inactivation. Reduction of virus infectivity caused by chemical or physical modification.

In Vitro Cell Age. A measure of the period between thawing of the MCB vial(s) and harvest of the production vessel measured by elapsed chronological time in culture, population doubling level of the cells, or passage level of the cells when subcultivated by a defined procedure for dilution of the culture.

Master Cell Bank (MCB). An aliquot of a single pool of cells which generally has been prepared from the selected cell clone under defined conditions, dispensed into multiple containers, and stored under defined conditions. The MCB is used to derive all working cell banks. The testing performed on a new MCB (from a previous initial cell clone, MCB, or WCB) should be the same as for the original MCB, unless justified.

Minimum Exposure Time. The shortest period for which a treatment step will be maintained.

Nonendogenous Virus. See Virus.

Process Characterization of Viral Clearance. Viral clearance studies in which nonspecific "model" viruses are used to assess the robustness of the manufacturing process to remove and/or inactivate viruses.

Process Evaluation Studies of Viral Clearance. Viral clearance studies in which "relevant" and/or specific "model" viruses are used to determine the ability of the manufacturing process to remove and/or inactivate these viruses.

Production Cells. Cell substrate used to manufacture product.

Unprocessed Bulk. One or multiple pooled harvests of cells and culture media. When cells are not readily accessible, the unprocessed bulk would constitute fluid harvested from the fermenter.

Virus. Intracellularly replicating infectious agents that are potentially pathogenic, possess only a single type of nucleic acid (either ribonucleic acid (RNA) or DNA), are unable to grow and undergo binary fission, and multiply in the form of their genetic material.

Adventitious Virus. Unintentionally introduced contaminant virus.

Endogenous Virus. Viral entity whose genome is part of the germ line of the species of origin of the cell line and is covalently integrated into the genome of animal from which the parental cell line was derived. For the purposes of this document, intentionally introduced, nonintegrated viruses such as EBV used to immortalize cell substrates or Bovine Papilloma Virus fit in this category.

Nonendogenous Virus. Virus from external sources present in the MCB.

Nonspecific Model Virus. A virus used for characterization of viral clearance of the process when the purpose is to characterize the capacity of the manufacturing process to remove and/or inactivate viruses in general, i.e., to characterize the robustness of the purification process.

Relevant Virus. Virus used in process evaluation studies which is either the identified virus, or of the same species as the virus that is known, or likely to contaminate the cell substrate or any other reagents or materials used in the production process.

specific Model Virus. Virus which is closely related to the known or suspected virus (same genus or family), having similar physical and chemical properties to those of the observed or suspected virus.

Viral Clearance. Elimination of target virus by removal of viral particles or inactivation of viral infectivity.

Virus-like Particles. Structures visible by electron microscopy which morphologically appear to be related to known viruses.

Virus Removal. Physical separation of virus particles from the intended product.

Working Cell Bank (WCB). The WCB is prepared from aliquots of a homogeneous suspension of cells obtained from culturing the MCB under defined culture conditions.

#### APPENDIX 1

##### Products Derived from Characterized Cell Banks Which Were Subsequently Grown In Vivo

For products manufactured from fluids harvested from animals inoculated with cells from characterized banks, additional information regarding the animals should be provided.

Whenever possible, animals used in the manufacture of biotechnological/biological products should be obtained from well defined, specific pathogen-free colonies. Adequate testing for appropriate viruses, such as those listed in [Table 3](#), should be performed. Quarantine procedures for newly arrived as well as diseased animals should be described, and assurance provided that all containment, cleaning, and decontamination methodologies employed within the facility are adequate to contain the spread of adventitious agents. This may be accomplished through the use of a sentinel program. A listing of agents for which testing is performed should also be included. Veterinary support services should be available on-site or within easy access. The degree to which the vivarium is segregated from other areas of the manufacturing facility should be described. Personnel practices should be adequate to ensure safety.

Procedures for the maintenance of the animals should be fully described. These would include diet, cleaning and feeding schedules, provisions for periodic veterinary care if applicable, and details of special handling that the animals may require once inoculated. A description of the priming regimen(s) for the animals, the preparation of the inoculum, and the site and route of inoculation should also be included.

The primary harvest material from animals may be considered an equivalent stage of manufacture to unprocessed bulk harvest from a bioreactor. Therefore, all testing considerations previously outlined in section IV. of this document should apply. In addition, the manufacturer should assess the bioburden of the unprocessed bulk, determine whether the material is free of mycoplasma, and perform species-specific assay(s) as well as in vivo testing in adult and suckling mice.

#### APPENDIX 2

##### The Choice of Viruses for Viral Clearance Studies

###### A. Examples of Useful "Model" Viruses:

###### 1. Nonspecific "model" viruses representing a range of physico-chemical structures:

- SV40 (Polyomavirus maccacae 1), human polio virus 1 (Sabin), animal parvovirus or some other small, nonenveloped viruses;
- a parainfluenza virus or influenza virus, Sindbis virus or some other medium-to-large, enveloped, RNA viruses;
- a herpes virus (e.g., HSV-1 or a pseudorabies virus), or some other medium-to-large, DNA viruses.

These viruses are examples only and their use is not mandatory.

###### 2. For rodent cell substrates murine retroviruses are commonly used as specific "model" viruses.

###### B. Examples of Viruses That Have Been Used in Viral Clearance Studies

Several viruses that have been used in viral clearance studies are listed in [Table A-1](#). However, since these are merely examples, the use of any of the viruses in the table is not considered mandatory and manufacturers are invited to consider other viruses, especially those that may be more appropriate for their individual production processes. Generally, the process should be assessed for its ability to clear at least three different viruses with differing characteristics.

#### APPENDIX 3

##### A. Statistical Considerations for Assessing Virus Assays

Virus titrations suffer the problems of variation common to all biological assay systems. Assessment of the accuracy of the virus titrations and reduction factors derived from them and the validity of the assays should be performed to define the reliability of a study. The objective of statistical evaluation is to establish that the study has been carried out to an acceptable level of virological competence.

1. Assay methods may be either quantal or quantitative. Quantal methods include infectivity assays in animals or in tissue-culture-infectious-dose (TCID) assays, in which the animal or cell culture is scored as either infected or not. Infectivity titers are then measured by the proportion of animals or culture infected. In quantitative methods, the infectivity measured varies continuously with the virus input. Quantitative methods include plaque assays where each plaque counted corresponds to a single infectious unit. Both quantal and quantitative assays are amenable to statistical evaluation.

2. Variation can arise within an assay as a result of dilution errors, statistical effects, and differences within the assay system which are either unknown or difficult to control. These effects are likely to be greater when different assay runs are compared (between-assay variation) than when results within a single assay run are compared (within-assay variation).

3. The 95 percent confidence limits for results of within-assay variation normally should be on the order of  $\pm 0.5 \log_{10}$  of the mean. Within-assay variation can be assessed by standard textbook methods. Between-assay variation can be monitored by the inclusion of a reference preparation, the estimate of whose potency should be within approximately  $0.5 \log_{10}$  of the mean estimate established in the laboratory for the assay to be acceptable. Assays with lower precision may be acceptable with appropriate justification.

4. The 95 percent confidence limits for the reduction factor observed should be calculated wherever possible in studies of clearance of "relevant" and specific "model" viruses. If the 95 percent confidence limits for the viral assays of the starting material are  $+s$ , and for the viral assays of the material after the step are  $+a$ , the 95 percent confidence limits for the reduction factor are

$$\pm \sqrt{s^2 + a^2}$$

###### B. Probability of Detection of Viruses at Low Concentrations

At low virus concentrations (e.g., in the range of 10 to 1,000 infectious particles per L) it is evident that a sample of a few milliliters may or may not contain infectious particles. The probability,  $p$ , that this sample does not contain infectious viruses is:

$$p = ((V-v) / V)n$$

where  $V$  (L) is the overall volume of the material to be tested;  $v$  (L) is the volume of the sample; and  $n$  is the absolute number of infectious particles statistically distributed in  $V$ .

If  $V \gg v$ , this equation can be approximated by the Poisson distribution:

$$p = e^{-cv}$$

where  $c$  is the concentration of infectious particles per L.

$$\text{or, } c = \ln p / -v$$

As an example, if a sample volume of 1 mL is tested, the probabilities  $p$  at virus concentrations ranging from 10 to 1,000 infectious particles per L are:

c	10	1,000
p	0.99	0.90

This indicates that for a concentration of 1,000 viruses per L, in 37 percent of sampling, 1 mL will not contain a virus particle.

If only a portion of a sample is tested for virus and the test is negative, the amount of virus which would have to be present in the total sample in order to achieve a positive result should be calculated and this value taken into account when calculating a reduction factor. Confidence limits at 95 percent are desirable. However, in some instances, this may not be practical due to material limitations.

#### APPENDIX 4

##### Calculation of Reduction Factors in Studies to Determine Viral Clearance

The virus reduction factor of an individual purification or inactivation step is defined as the  $\log_{10}$  of the ratio of the virus load in the pre-purification material and the virus load in the post-purification material which is ready for use in the next step of the process. If the following abbreviations are used:

Starting material: vol  $v'$ ; titer  $10a'$ ;

virus load:  $(v')(10a')$ ,

Final material: vol  $v''$ ; titer  $10a''$ ;

virus load:  $(v'')(10a'')$ ,

the individual reduction factors  $R_i$  are calculated according to

$$10R_i = (v')(10a') / (v'')(10a'')$$

This formula takes into account both the titers and volumes of the materials before and after the purification step.

Because of the inherent imprecision of some virus titrations, an individual reduction factor used for the calculation of an overall reduction factor should be greater than 1.

The overall reduction factor for a complete production process is the sum logarithm of the reduction factors of the individual steps. It represents the logarithm of the ratio of the virus load at the beginning of the first process clearance step and at the end of the last process clearance step. Reduction factors are normally expressed on a logarithmic scale which implies that, while residual virus infectivity will never be reduced to zero, it may be greatly reduced mathematically.

#### APPENDIX 5

##### Calculation of Estimated Particles per Dose

This is applicable to those viruses for which an estimate of starting numbers can be made, such as endogenous retroviruses.

Example:

###### I. Assumptions

Measured or estimated concentration of virus in cell culture harvest =  $10^6$ /mL

Calculated viral clearance factor =  $> 10^{15}$

Volume of culture harvest needed to make a dose of product = 1 L (103 mL)

###### II. Calculation of Estimated Particles/Dose

$$\begin{aligned} & \frac{(10^6 \text{ virus units/mL}) \times (10^3 \text{ mL/dose})}{\text{Clearance factor} > 10^{15}} \\ &= \frac{10^9 \text{ particles/dose}}{\text{Clearance factor} > 10^{15}} \\ &= < 10^{-6} \text{ particles/dose} \end{aligned}$$

Therefore, less than one particle per million doses would be expected.

#### 1051 CLEANING GLASS APPARATUS

Success in conducting many Pharmacopeial assays and tests depends upon the utmost cleanliness of the glassware apparatus used. For example, the accuracy of the assays of heparin sodium and vitamin B12 activity, as well as the pyrogen and total organic carbon tests, are particularly dependent upon scrupulously clean glassware.

One effective method used in the past for cleaning glassware is the application of hot nitric acid. A second traditional method for removing organic matter that does not require heat is the use of a chromic acid-sulfuric acid mixture. However, the chromic acid wash is not recommended because of the hazardous and toxic nature of the material.

Several safer alternatives, including the use of cleansing agents, such as trisodium phosphate and synthetic detergents, have proven highly useful, but require prolonged rinsing. It may be useful to rinse with diluted nitric or sulfuric acid prior to rinsing with water. This operation will facilitate removal of residual alkaline material.

For optical measurements, special care is required for cleaning containers, but the use of both chromic acid and highly alkaline solutions should be avoided.

Effective removal of organic matter is very important for testing pharmaceutical waters in accordance with the general test chapter [Total Organic Carbon \(643\)](#). It has been demonstrated that an alkaline detergent with potassium hydroxide as the primary ingredient\* leaves the least amount of organic matter residuals. Heating in a muffle furnace produces comparable results and is the least labor-intensive procedure; however, it requires specialized equipment.

In all cases, it is important to verify that the cleaning procedure is appropriate for the particular test or assay being undertaken. This can be accomplished via blank runs, scientific judgments, residuals data from cleansing agent and detergent manufacturers, or other controls. Specifically, special care is required for cleaning containers for optical measurement applications; the use of highly alkaline and the no longer recommended chromic acid solutions should be avoided. Finally, a statement should be included in the cleaning protocol describing how the success of the cleaning procedure will be assessed.

### 1052 BIOTECHNOLOGY-DERIVED ARTICLES—AMINO ACID ANALYSIS

This chapter provides guidance and procedures used for characterization of biotechnology-derived articles by amino acid analysis. This chapter is harmonized with the corresponding chapter in JP and EP. Other characterization tests, also harmonized, are shown in [Biotechnology-Derived Articles—Capillary Electrophoresis \(1053\)](#), [Biotechnology-Derived Articles—Isoelectric Focusing \(1054\)](#), [Biotechnology-Derived Articles—Peptide Mapping \(1055\)](#), [Biotechnology-Derived Articles—Polyacrylamide Gel Electrophoresis \(1056\)](#), and [Biotechnology-Derived Articles—Total Protein Assay \(1057\)](#).

#### INTRODUCTION

Amino acid analysis refers to the methodology used to determine the amino acid composition or content of proteins, peptides, and other pharmaceutical preparations. Proteins and peptides are macromolecules consisting of covalently bonded amino acid residues organized as a linear polymer. The sequence of the amino acids in a protein or peptide determines the properties of the molecule. Proteins are considered large molecules that commonly exist as folded structures with a specific conformation, while peptides are smaller and may consist of only a few amino acids. Amino acid analysis can be used to quantify protein and peptides, to determine the identity of proteins or peptides based on their amino acid composition, to support protein and peptide structure analysis, to evaluate fragmentation strategies for peptide mapping, and to detect atypical amino acids that might be present in a protein or peptide. It is necessary to hydrolyze a protein/peptide to its individual amino acid constituents before amino acid analysis. Following protein/peptide hydrolysis, the amino acid analysis procedure can be the same as that practiced for free amino acids in other pharmaceutical preparations. The amino acid constituents of the test sample are typically derivatized for analysis.

#### APPARATUS

Methods used for amino acid analysis are usually based on a chromatographic separation of the amino acids present in the test sample. Current techniques take advantage of the automated chromatographic instrumentation designed for analytical methodologies. An amino acid analysis instrument will typically be a low-pressure or high-pressure liquid chromatograph capable of generating mobile phase gradients that separate the amino acid analytes on a chromatographic column. The instrument must have postcolumn derivatization capability, unless the sample is analyzed using precolumn derivatization. The detector is usually a UV-visible or fluorescence detector depending on the derivatization method used. A recording device (e.g., integrator) is used for transforming the analog signal from the detector and for quantitation. It is preferred that instrumentation be dedicated particularly for amino acid analysis.

#### GENERAL PRECAUTIONS

Background contamination is always a concern for the analyst in performing amino acid analysis. High-purity reagents are necessary (e.g., low-purity hydrochloric acid can contribute to glycine contamination). Analytical reagents are changed routinely every few weeks using only high-pressure liquid chromatography (HPLC) grade solvents. Potential microbial contamination and foreign material that might be present in the solvents are reduced by filtering solvents before use, keeping solvent reservoirs covered, and not placing amino acid analysis instrumentation in direct sunlight.

Laboratory practices can determine the quality of the amino acid analysis. Place the instrumentation in a low traffic area of the laboratory. Keep the laboratory clean. Clean and calibrate pipets according to a maintenance schedule. Keep pipet tips in a covered box; the analysts may not handle pipet tips with their hands. The analysts may wear powder-free latex or equivalent gloves. Limit the number of times a test sample vial is opened and closed because dust can contribute to elevated levels of glycine, serine, and alanine.

A well-maintained instrument is necessary for acceptable amino acid analysis results. If the instrument is used on a routine basis, it is to be checked daily for leaks, detector and lamp stability, and the ability of the column to maintain resolution of the individual amino acids. Clean or replace all instrument filters and other maintenance items on a routine schedule.

#### REFERENCE STANDARD MATERIAL

Acceptable amino acid standards are commercially available\* for amino acid analysis and typically consist of an aqueous mixture of amino acids. When determining amino acid composition, protein or peptide standards are analyzed with the test material as a control to demonstrate the integrity of the entire procedure. Highly purified bovine serum albumin has been used as a protein standard for this purpose.

#### CALIBRATION OF INSTRUMENTATION

Calibration of amino acid analysis instrumentation typically involves analyzing the amino acid standard, which consists of a mixture of amino acids at a number of concentrations, to determine the response factor and range of analysis for each amino acid. The concentration of each amino acid in the standard is known. In the calibration procedure, the analyst dilutes the amino acid standard to several different analyte levels within the expected linear range of the amino acid analysis technique. Then, replicates at each of the different analyte levels can be analyzed. Peak areas obtained for each amino acid are plotted versus the known concentration for each of the amino acids in the standard dilution. These results will allow the analyst to determine the range of amino acid concentrations where the peak area of a given amino acid is an approximately linear function of the amino acid concentration. It is important that the analyst prepare the samples for amino acid analysis so that they are within the analytical limits (e.g., linear working range) of the technique employed in order to obtain accurate and repeatable results.

Four to six amino acid standard levels are analyzed to determine a response factor for each amino acid. The response factor is calculated as the average peak area or peak height per nmol of amino acid present in the standard. A calibration file consisting of the response factor for each amino acid is prepared and is used to calculate the concentration of each amino acid present in the test sample. This calculation involves dividing the peak area corresponding to a given amino acid by the response factor for that amino acid to give the nmol of the amino acid. For routine analysis, a single-point calibration may be sufficient; however, the calibration file is updated frequently and tested by the analysis of analytical controls to ensure

its integrity.

#### REPEATABILITY

Consistent high quality amino acid analysis results from an analytical laboratory require attention to the repeatability of the assay. During analysis of the chromatographic separation of the amino acids or their derivatives, numerous peaks can be observed on the chromatogram that corresponds to the amino acids. The large number of peaks makes it necessary to have an amino acid analysis system that can repeatedly identify the peaks based on retention time and integrate the peak areas for quantitation. A typical repeatability evaluation involves preparing a standard amino acid solution and analyzing many replicates (i.e., six analyses or more) of the same standard solution. The relative standard deviation (RSD) is determined for the retention time and integrated peak area of each amino acid. An evaluation of the repeatability is expanded to include multiple assays conducted over several days by different analysts. Multiple assays include the preparation of standard dilutions from starting materials to determine the variation due to sample handling. Often, the amino acid composition of a standard protein (e.g., bovine serum albumin) is analyzed as part of the repeatability evaluation. By evaluating the replicate variation (i.e., RSD), the laboratory can establish analytical limits to ensure that the analyses from the laboratory are under control. It is desirable to establish the lowest practical variation limits to ensure the best results.

Areas to focus on to lower the variability of the amino acid analysis include sample preparation, high background spectral interference due to the quality of reagents and/or to laboratory practices, instrument performance and maintenance, data analysis and interpretation, and analyst performance and habits. All parameters involved are fully investigated in the scope of the validation work.

#### SAMPLE PREPARATION

Accurate results from amino acid analysis require purified protein and peptide samples. Buffer components (e.g., salts, urea, detergents) can interfere with the amino acid analysis and are removed from the sample before analysis. Methods that utilize postcolumn derivatization of the amino acids are generally not affected by buffer components to the extent seen with precolumn derivatization methods. It is desirable to limit the number of sample manipulations to reduce potential background contamination, to improve analyte recovery, and to reduce labor. Common techniques used to remove buffer components from protein samples include the following methods: (1) injecting the protein sample onto a reverse-phase HPLC system, removing the protein with a volatile solvent containing a sufficient organic component, and drying the sample in a vacuum centrifuge; (2) dialysis against a volatile buffer or water; (3) centrifugal ultrafiltration for buffer replacement with a volatile buffer or water; (4) precipitating the protein from the buffer using an organic solvent (e.g., acetone); and (5) gel filtration.

#### INTERNAL STANDARDS

It is recommended that an internal standard be used to monitor physical and chemical losses and variations during amino acid analysis. An accurately known amount of internal standard can be added to a protein solution prior to hydrolysis. The recovery of the internal standard gives the general recovery of the amino acids from the protein solution. Free amino acids, however, do not behave in the same way as protein-bound amino acids during hydrolysis because their rates of release or destruction are variable. Therefore, the use of an internal standard to correct for losses during hydrolysis may give unreliable results. It will be necessary to take this particular point into consideration when interpreting the results.

Internal standards can also be added to the mixture of amino acids after hydrolysis to correct for differences in sample application and changes in reagent stability and flow rates. Ideally, an internal standard is an unnaturally occurring primary amino acid that is commercially available and inexpensive. It should also be stable during hydrolysis, its response factor should be linear with concentration, and it needs to elute with a unique retention time without overlapping other amino acids. Commonly used amino acid standards include norleucine, nitrotyrosine, and  $\alpha$ -aminobutyric acid.

#### PROTEIN HYDROLYSIS

Hydrolysis of protein and peptide samples is necessary for amino acid analysis of these molecules. The glassware used for hydrolysis must be very clean to avoid erroneous results.

Glove powders and fingerprints on hydrolysis tubes may cause contamination. To clean glass hydrolysis tubes, boil tubes for 1 hour in 1 N hydrochloric acid or soak tubes in concentrated nitric acid or in a mixture of concentrated hydrochloric acid and concentrated nitric acid (1:1). Clean hydrolysis tubes are rinsed with high-purity water followed by a rinse with HPLC grade methanol, dried overnight in an oven, and stored covered until use. Alternatively, pyrolysis of clean glassware at 500 $^{\circ}$  for 4 hours may be used to eliminate contamination from hydrolysis tubes. Adequate disposable laboratory material can also be used.

Acid hydrolysis is the most common method for hydrolyzing a protein sample before amino acid analysis. The acid hydrolysis technique can contribute to the variation of the analysis due to complete or partial destruction of several amino acids. Tryptophan is destroyed; serine and threonine are partially destroyed; methionine might undergo oxidation; and cysteine is typically recovered as cystine (but cystine recovery is usually poor because of partial destruction or reduction to cysteine). Application of adequate vacuum (less than 200  $\mu$ m of mercury or 26.7 Pa) or introduction of an inert gas (argon) in the headspace of the reaction vessel can reduce the level of oxidative destruction. In peptide bonds involving isoleucine and valine, the amido bonds of Ile-Ile, Val-Val, Ile-Val, and Val-Ile are partially cleaved; and asparagine and glutamine are deamidated, resulting in aspartic acid and glutamic acid, respectively. The loss of tryptophan, asparagine, and glutamine during an acid hydrolysis limits quantitation to 17 amino acids. Some of the hydrolysis techniques described are used to address these concerns. Some of the hydrolysis techniques described (i.e., Methods 4–11) may cause modifications to other amino acids. Therefore, the benefits of using a given hydrolysis technique are weighed against the concerns with the technique and are tested adequately before employing a method other than acid hydrolysis.

A time-course study (i.e., amino acid analysis at acid hydrolysis times of 24, 48, and 72 hours) is often employed to analyze the starting concentration of amino acids that are partially destroyed or slow to cleave. By plotting the observed concentration of labile amino acids (i.e., serine and threonine) versus hydrolysis time, the line can be extrapolated to the origin to determine the starting concentration of these amino acids. Time-course hydrolysis studies are also used with amino acids that are slow to cleave (e.g., isoleucine and valine). During the hydrolysis time course, the analyst will observe a plateau in these residues. The level of this plateau is taken as the residue concentration. If the hydrolysis time is too long, the residue concentration of the sample will begin to decrease, indicating destruction by the hydrolysis conditions.

An acceptable alternative to the time-course study is to subject an amino acid calibration standard to the same hydrolysis conditions as the test sample. The amino acid in free form may not completely represent the rate of destruction of labile amino acids within a peptide or protein during the hydrolysis. This is especially true for peptide bonds that are slow to cleave (e.g., Ile-Val bonds). However, this technique will allow the analyst to account for some residue destruction. Microwave acid hydrolysis has been used and is rapid but it requires special equipment as well as special precautions. The optimal conditions for microwave hydrolysis must be investigated for each individual protein/peptide sample. The microwave hydrolysis technique typically requires only a few minutes, but even a deviation of 1 minute may give inadequate results (e.g., incomplete hydrolysis or destruction of labile amino acids). Complete proteolysis, using a mixture of proteases, has been used but can be complicated, requires the proper controls, and is typically more applicable to peptides than proteins. [note—During initial analyses of an unknown protein, experiments with various hydrolysis time and temperature conditions are conducted to determine the optimal conditions.]

#### Method 1

Acid hydrolysis using hydrochloric acid containing phenol is the most common procedure used for protein/peptide hydrolysis preceding amino acid analysis. The addition of phenol to the reaction prevents the halogenation of tyrosine.

Hydrolysis Solution: 6 N hydrochloric acid containing 0.1% to 1.0% of phenol.

#### Procedure—

Liquid Phase Hydrolysis—Place the protein or peptide sample in a hydrolysis tube, and dry. [note—The sample is dried so that water in the sample will not dilute the acid used for the hydrolysis.] Add 200  $\mu$ L of Hydrolysis Solution per 500  $\mu$ g of lyophilized protein. Freeze the sample tube in a dry ice–acetone bath, and flame seal in vacuum. Samples are typically hydrolyzed at 110 $^{\circ}$  for 24 hours in vacuum or inert atmosphere to prevent oxidation. Longer hydrolysis times (e.g., 48 and 72 hours) are investigated if there is a concern that the protein is not completely hydrolyzed.

Vapor Phase Hydrolysis—This is one of the most common acid hydrolysis procedures, and it is preferred for microanalysis when only small amounts of the sample are available. Contamination of the sample from the acid reagent is also minimized by using vapor phase hydrolysis. Place vials containing the dried samples in a vessel that contains an appropriate amount of Hydrolysis Solution. The Hydrolysis Solution does not come in contact with the test sample. Apply an inert atmosphere or vacuum (less than 200  $\mu$ m of mercury or 26.7 Pa)

to the headspace of the vessel, and heat to about  $110^{\circ}\text{C}$  for a 24-hour hydrolysis time. Acid vapor hydrolyzes the dried sample. Any condensation of the acid in the sample vials is minimized. After hydrolysis, dry the test sample in vacuum to remove any residual acid.

#### Method 2

Tryptophan oxidation during hydrolysis is decreased by using mercaptoethanesulfonic acid (MESA) as the reducing acid.

Hydrolysis Solution: 2.5 M MESA solution.

Vapor Phase Hydrolysis— About 1 to 100  $\mu\text{g}$  of the protein/peptide under test is dried in a hydrolysis tube. The hydrolysis tube is placed in a larger tube with about 200  $\mu\text{L}$  of the Hydrolysis Solution. The larger tube is sealed in vacuum (about 50  $\mu\text{m}$  of mercury or 6.7 Pa) to vaporize the Hydrolysis Solution. The hydrolysis tube is heated to between  $170^{\circ}\text{C}$  to  $185^{\circ}\text{C}$  for about 12.5 minutes. After hydrolysis, the hydrolysis tube is dried in vacuum for 15 minutes to remove the residual acid.

#### Method 3

Tryptophan oxidation during hydrolysis is prevented by using thioglycolic acid (TGA) as the reducing acid.

Hydrolysis Solution: a solution containing 7 M hydrochloric acid, 10% of trifluoroacetic acid, 20% of thioglycolic acid, and 1% of phenol.

Vapor Phase Hydrolysis— About 10 to 50  $\mu\text{g}$  of the protein/peptide under test is dried in a sample tube. The sample tube is placed in a larger tube with about 200  $\mu\text{L}$  of the Hydrolysis Solution. The larger tube is sealed in vacuum (about 50  $\mu\text{m}$  of mercury or 6.7 Pa) to vaporize the TGA. The sample tube is heated to  $166^{\circ}\text{C}$  for about 15 to 30 minutes. After hydrolysis, the sample tube is dried in vacuum for 5 minutes to remove the residual acid. Recovery of tryptophan by this method may be dependent on the amount of sample present.

#### Method 4

Cysteine-cystine and methionine oxidation is performed with formic acid before the protein hydrolysis.

Oxidation Solution— The formic acid is prepared fresh by mixing formic acid and 30 percent hydrogen peroxide (9:1), and incubating at room temperature for 1 hour.

Procedure— The protein/peptide sample is dissolved in 20  $\mu\text{L}$  of formic acid, and heated at  $50^{\circ}\text{C}$  for 5 minutes; then 100  $\mu\text{L}$  of the Oxidation Solution is added. In this reaction, cysteine is converted to cysteic acid and methionine is converted to methionine sulfone. The oxidation is allowed to proceed for 10 to 30 minutes. The excess reagent is removed from the sample in a vacuum centrifuge. This technique may cause modifications to tyrosine residues in the presence of halides. The oxidized protein can then be acid hydrolyzed using Method 1 or Method 2.

#### Method 5

Cysteine-cystine oxidation is accomplished during the liquid phase hydrolysis with sodium azide.

Hydrolysis Solution: 6 N hydrochloric acid containing 0.2% of phenol, to which sodium azide is added to obtain a final concentration of 0.2% (w/v). The added phenol prevents halogenation of tyrosine.

Liquid Phase Hydrolysis— The protein/peptide hydrolysis is conducted at about  $110^{\circ}\text{C}$  for 24 hours. During the hydrolysis, the cysteine-cystine present in the sample is converted to cysteic acid by the sodium azide present in the Hydrolysis Solution. This technique allows better tyrosine recovery than Method 4, but it is not quantitative for methionine. Methionine is converted to a mixture of the parent methionine and its two oxidative products, methionine sulfoxide and methionine sulfone.

#### Method 6

Cysteine-cystine oxidation is accomplished with dimethyl sulfoxide (DMSO).

Hydrolysis Solution: 6 N hydrochloric acid containing 0.1% to 1.0% of phenol, to which DMSO is added to obtain a final concentration of 2% (v/v).

Vapor Phase Hydrolysis— The protein/peptide hydrolysis is conducted at about  $110^{\circ}\text{C}$  for 24 hours. During the hydrolysis, the cysteine-cystine present in the sample is converted to cysteic acid by the DMSO present in the Hydrolysis Solution. As an approach to limit variability and to compensate for partial destruction, it is recommended to evaluate the cysteic acid recovery from oxidative hydrolyses of standard proteins containing 1 to 8 mol of cysteine. The response factors from protein/peptide hydrolysates are typically about 30% lower than those for nonhydrolyzed cysteic acid standards. Because histidine, methionine, tyrosine, and tryptophan are also modified, a complete compositional analysis is not obtained with this technique.

#### Method 7

Cysteine-cystine reduction and alkylation is accomplished by a vapor phase pyridylethylation reaction.

Reducing Solution— Transfer 83.3  $\mu\text{L}$  of pyridine, 16.7  $\mu\text{L}$  of 4-vinylpyridine, 16.7  $\mu\text{L}$  of tributylphosphine, and 83.3  $\mu\text{L}$  of water to a suitable container, and mix.

Procedure— Add the protein/peptide (between 1 and 100  $\mu\text{g}$ ) to a hydrolysis tube, and place in a larger tube. Transfer the Reducing Solution to the large tube, seal in vacuum (about 50  $\mu\text{m}$  of mercury or 6.7 Pa), and incubate at about  $100^{\circ}\text{C}$  for 5 minutes. Then remove the inner hydrolysis tube, and dry it in a vacuum desiccator for 15 minutes to remove residual reagents. The pyridylethylated protein/peptide can then be acid hydrolyzed using previously described procedures. The pyridylethylation reaction is performed simultaneously with a protein standard sample containing 1 to 8 mol of cysteine to improve accuracy in the pyridylethyl-cysteine recovery. Longer incubation times for the pyridylethylation reaction can cause modifications to the  $\alpha$ -amino terminal group and the  $\epsilon$ -amino group of lysine in the protein.

#### Method 8

Cysteine-cystine reduction and alkylation is accomplished by a liquid phase pyridylethylation reaction.

Stock Solutions— Prepare and filter three solutions: 1 M Tris hydrochloride (pH 8.5) containing 4 mM edetate disodium (Stock Solution 1), 8 M guanidine hydrochloride (Stock Solution 2), and 10% of 2-mercaptopropanoic acid in water (Stock Solution 3).

Reducing Solution— Prepare a mixture of Stock Solution 2 and Stock Solution 1 (3:1) to obtain a buffered solution of 6 M guanidine hydrochloride in 0.25 M Tris hydrochloride.

Procedure— Dissolve about 10  $\mu\text{g}$  of the test sample in 50  $\mu\text{L}$  of the Reducing Solution, and add about 2.5  $\mu\text{L}$  of Stock Solution 3. Store under nitrogen or argon for 2 hours at room temperature in the dark. To achieve the pyridylethylation reaction, add about 2  $\mu\text{L}$  of 4-vinylpyridine to the protein solution, and incubate for an additional 2 hours at room temperature in the dark. The protein/peptide is desalted by collecting the protein/peptide fraction from a reverse-phase HPLC separation. The collected sample can be dried in a vacuum centrifuge before acid hydrolysis.

#### Method 9

Cysteine-cystine reduction and alkylation is accomplished by a liquid phase carboxymethylation reaction.

Stock Solutions— Prepare as directed for Method 8.

Carboxymethylation Solution— Prepare a solution containing 100 mg of iodoacetamide per mL of alcohol.

Buffer Solution— Use the Reducing Solution, prepared as directed for Method 8.

Procedure— Dissolve the test sample in 50  $\mu\text{L}$  of the Buffer Solution, and add about 2.5  $\mu\text{L}$  of Stock Solution 3. Store under nitrogen or argon for 2 hours at room temperature in the dark. Add the Carboxymethylation Solution in a 1.5 fold ratio per total theoretical content of thiols, and incubate for an additional 30 minutes at room temperature in the dark. [note—If the thiol content of the protein is unknown, then add 5  $\mu\text{L}$  of 100 mM iodoacetamide for every 20 nmol of protein present.] The reaction is stopped by adding excess of 2-mercaptopropanoic acid. The protein/peptide is desalted by collecting the protein/peptide fraction from a reverse-phase HPLC separation. The collected sample can be dried in a vacuum

centrifuge before acid hydrolysis. The S-carboxyamidomethylcysteine formed will be converted to S-carboxymethyl-cysteine during acid hydrolysis.

#### Method 10

Cysteine-cystine is reacted with dithiodiglycolic acid or dithiodipropionic acid to produce a mixed disulfide. [note—The choice of dithiodiglycolic acid or dithiodipropionic acid depends on the required resolution of the amino acid analysis method.]

Reducing Solution: a solution containing 10 mg of dithiodiglycolic acid (or dithiodipropionic acid) per mL of 0.2 M sodium hydroxide.

Procedure— Transfer about 20 µg of the test sample to a hydrolysis tube, and add 5 µL of the Reducing Solution. Add 10 µL of isopropyl alcohol, and then remove all of the sample liquid by vacuum centrifugation. The sample is then hydrolyzed using Method 1. This method has the advantage that other amino acid residues are not derivatized by side reactions, and the sample does not need to be desalted prior to hydrolysis.

#### Method 11

Asparagine and glutamine are converted to aspartic acid and glutamic acid, respectively, during acid hydrolysis. Asparagine and aspartic acid residues are added and represented by Asx, while glutamine and glutamic acid residues are added and represented by Glx. Proteins/peptides can be reacted with bis(1,1-trifluoroacetoxy)iodobenzene (BTI) to convert the asparagine and glutamine residues to diaminopropionic acid and diaminobutyric acid residues, respectively, upon acid hydrolysis. These conversions allow the analyst to determine the asparagine and glutamine content of a protein/peptide in the presence of aspartic acid and glutamic acid residues.

Reducing Solutions— Prepare and filter three solutions: a solution of 10 mM trifluoroacetic acid (Solution 1), a solution of 5 M guanidine hydrochloride and 10 mM trifluoroacetic acid (Solution 2), and a freshly prepared solution of dimethylformamide containing 36 mg of BTI per mL (Solution 3).

Procedure— In a clean hydrolysis tube, transfer about 200 µg of the test sample, and add 2 mL of Solution 1 or Solution 2 and 2 mL of Solution 3. Seal the hydrolysis tube in vacuum. Heat the sample at 60° for 4 hours in the dark. The sample is then dialyzed with water to remove the excess reagents. Extract the dialyzed sample three times with equal volumes of n-butyl acetate, and then lyophilize. The protein can then be acid hydrolyzed using previously described procedures. The  $\alpha$ -,  $\beta$ -diaminopropionic and  $\alpha$ -,  $\gamma$ -diaminobutyric acid residues do not typically resolve from the lysine residues upon ion-exchange chromatography based on amino acid analysis. Therefore, when using ion-exchange as the mode of amino acid separation, the asparagine and glutamine contents are the quantitative difference in the aspartic acid and glutamic acid assayed contents with un-derivatized and BTI-derivatized acid hydrolysis. [note—The threonine, methionine, cysteine, tyrosine, and histidine assayed content can be altered by BTI derivatization; a hydrolysis without BTI will have to be performed if the analyst is interested in the protein/peptide content of these other amino acid residues.]

### METHODOLOGIES OF AMINO ACID ANALYSIS

Many amino acid analysis techniques exist, and the choice of any one technique often depends on the sensitivity required from the assay. In general, about one-half of the amino acid analysis techniques employed rely on the separation of the free amino acids by ion-exchange chromatography followed by postcolumn derivatization (e.g., with ninhydrin or o-phthalaldehyde). Postcolumn detection techniques can be used with samples that contain small amounts of buffer components, such as salts and urea, and generally require between 5 and 10 µg of protein sample per analysis. The remaining amino acid techniques typically involve precolumn derivatization of the free amino acids (e.g., phenyl isothiocyanate; 6-aminoquinolyl-N-hydroxysuccinimidyl carbonate; (dimethylamino)azobenzenesulfonyl chloride; 9-fluorenyl-methylchloroformate; and 7-fluoro-4-nitrobenzo-2-oxa-1,3-diazole) followed by reverse-phase HPLC. Precolumn derivatization techniques are very sensitive and usually require between 0.5 and 1.0 µg of protein sample per analysis but may be influenced by buffer salts in the samples. Precolumn derivatization techniques may also result in multiple derivatives of a given amino acid, which complicates the result interpretation. Postcolumn derivatization techniques are generally influenced less by performance variation of the assay than precolumn derivatization techniques.

The following Methods may be used for quantitative amino acid analysis. Instruments and reagents for these procedures are available commercially. Furthermore, many modifications of these methodologies exist with different reagent preparations, reaction procedures, and chromatographic systems. Specific parameters may vary according to the exact equipment and procedure used. Many laboratories will utilize more than one amino acid analysis technique to exploit the advantages offered by each. In each of these Methods, the analog signal is visualized by means of a data acquisition system, and the peak areas are integrated for quantification purposes.

#### Method 1—Postcolumn Ninhydrin Detection

Ion-exchange chromatography with postcolumn ninhydrin detection is one of the most common methods employed for quantitative amino acid analysis. As a rule, a Li-based cation-exchange system is employed for the analysis of the more complex physiological samples, and the faster Na-based cation-exchange system is used for the more simplistic amino acid mixtures obtained with protein hydrolysates (typically containing 17 amino acid components). Separation of the amino acids on an ion-exchange column is accomplished through a combination of changes in pH and cation strength. A temperature gradient is often employed to enhance separation.

When the amino acid reacts with ninhydrin, the reactant has characteristic purple or yellow color. Amino acids, except imino acids, give a purple color, and show maximum absorption at 570 nm. The imino acids, such as proline, give a yellow color, and show maximum absorption at 440 nm. The postcolumn reaction between ninhydrin and amino acid eluted from the column is monitored at 440 nm and 570 nm, and the chromatogram obtained is used for the determination of amino acid composition.

The detection limit is considered to be 10 pmol for most of the amino acid derivatives, but 50 pmol for proline. Response linearity is obtained in the range of 20 to 500 pmol with correlation coefficients exceeding 0.999. To obtain good compositional data, samples larger than 1 µg before hydrolysis are best suited for this amino acid analysis of protein/peptide.

One method for postcolumn ninhydrin detection is shown below. Many other methods are also available, with instruments and reagents available commercially.

##### Mobile Phase Preparation—

Solution A— Transfer about 1.7 g of anhydrous sodium citrate and 1.5 mL of hydrochloric acid to a 100-mL volumetric flask, dissolve in and dilute with water to volume, and mix. Adjust, if necessary, with hydrochloric acid to a pH of 3.0.

Solution B— Transfer about 1.7 g of anhydrous sodium citrate and 0.7 mL of hydrochloric acid to a 100-mL volumetric flask, dissolve in and dilute with water to volume, and mix. Adjust, if necessary, with hydrochloric acid to a pH of 4.3.

Solution C— Prepare a solution containing 5% of sodium chloride, 1.9% of anhydrous sodium citrate, and 0.1% of phenol in water, and adjust to a pH of 6.

Column Regeneration Solution— Prepare a solution containing 0.8% of sodium hydroxide in water, and adjust to a pH of 13.

Mobile Phase— Use variable mixtures of Solution A, Solution B, and Solution C as directed for Chromatographic System.

Postcolumn Reagent— Transfer about 18 g of ninhydrin and 0.7 g of hydrindantin to 900 mL of a solution containing 76.7% of dimethyl sulfoxide, 0.7% of dihydrate lithium acetate, and 0.1% of acetic acid, and mix for at least 3 hours under inert gas, such as nitrogen. [note—This reagent is stable for 30 days if kept between 2° and 8° under inert gas.]

Buffer Solution— Prepare a solution containing 2% of anhydrous sodium citrate, 1% of hydrochloric acid, 0.5% of thiodiglycol, and 0.1% of benzoic acid in water, and adjust to a pH of 2.

Chromatographic System— The liquid chromatograph is equipped with a detector with appropriate interference filters at 440, 570, or 690 nm and a 4.0-mm  $\times$  120-mm column that contains 7.5-µm sulfonated styrene-divinylbenzene copolymer packing. The flow rate is about 14 mL per hour. The system is programmed as follows. Initially equilibrate the column with Solution A; at 25 minutes, the composition of the Mobile Phase is changed to 100% Solution B; and at 37 minutes, the composition is changed to 100% Solution C. At 75 minutes into the run, the last amino acid has been eluted from the column, and the column is regenerated with Column Regeneration Solution for 1 minute. The column is then equilibrated with Solution A for 11 minutes before the next injection. The column temperature is programmed as follows. The initial temperature is 48°; after 11.5 minutes, the temperature is increased to 65° at a rate of 3° per minute; at about 35 minutes, the temperature is increased to 77° at a rate of 3° per minute; and finally at about 52 minutes, the temperature is decreased to 48° at a rate of 3° per minute.

Procedure and Postcolumn Reaction— Reconstitute the lyophilized protein/peptide hydrolysate in the Buffer Solution, inject an appropriate amount into the chromatograph, and proceed as directed for Chromatographic System. As the amino acids are eluted from the column, they are mixed with the Postcolumn Reagent, which is delivered at a flow rate of 7

ML per hour, through a tee. After mixing, the column effluent and the Postcolumn Reagent pass through a tubular reactor at a temperature of 135°, where a characteristic purple or yellow color is developed. From the reactor, the liquid passes through a colorimeter with a 12-mm flow-through cuvette. The light emerging from the cuvette is split into three beams for analysis by the detector with interference filters at 440, 570, or 690 nm. The 690-nm signal may be electronically subtracted from the other signals for improved signal-to-noise ratios.

The 440-nm (imino acids) and the 570-nm (amino acids) signals may be added in order to simplify data handling.

#### Method 2—Postcolumn OPA Fluorometric Derivatization

Ion-exchange chromatography with postcolumn o-phthalaldehyde (OPA) fluorometric detection is used. The procedure employs an ion-exchange column for separation of free amino acids followed by postcolumn oxidation with sodium hypochlorite and derivatization using OPA and N-acetyl-l-cysteine. The sodium hypochlorite oxidation step allows secondary amines, such as proline, to react with the OPA reagent.

OPA reacts with primary amines in the presence of thiol compound to form highly fluorescent isoindole products. This reaction is utilized for the postcolumn derivatization in analysis of amino acids by ion-exchange chromatography. The rule of the separation is the same as Method I. Instruments and reagents for this form of amino acid analysis are available commercially. Many modifications of this method exist.

Although OPA does not react with secondary amines (imino acids, such as proline) to form fluorescent substances, the oxidation with sodium hypochlorite allows secondary amines to react with OPA. The procedure employs a strongly acidic cation-exchange column for separation of free amino acids followed by postcolumn oxidation with sodium hypochlorite and postcolumn derivatization using OPA and thiol compound, such as N-acetyl-l-cysteine and 2-mercaptoethanol. The derivatization of primary amino acids are not noticeably affected by the continuous supply of sodium hypochlorite.

Separation of the amino acids on an ion-exchange column is accomplished through a combination of changes of pH and cation strength. After postcolumn derivatization of eluted amino acids with OPA, the reactant passes through the fluorometric detector. Fluorescence intensity of OPA-derivatized amino acids are monitored with an excitation wavelength of 348 nm and an emission wavelength of 450 nm.

The detection limit is considered to be a few tens of pmol level for most of the amino acid derivatives. Response linearity is obtained in the range of a few pmol level to a few tens of nmol level. To obtain good compositional data, a sample greater than 500 ng before hydrolysis is best suited for the amino acid analysis of protein/peptide.

One method of postcolumn OPA fluorometric detection is shown below.

#### Mobile Phase Preparation—

Solution A— Prepare a solution of sodium hydroxide, citric acid, and alcohol in HPLC grade water having a 0.2 N sodium concentration and containing 7% of alcohol (w/v), adjusted to a pH of 3.2.

Solution B— Prepare a solution of sodium hydroxide and citric acid in HPLC grade water having a 0.6 N sodium concentration, adjusted to a pH of 10.0.

Solution C: 0.2 N sodium hydroxide.

Mobile Phase— Use variable mixtures of Solution A, Solution B, and Solution C as directed for Chromatographic System.

#### Postcolumn Reagent Preparation—

Alkaline Buffer— Prepare a solution containing 384 mM sodium carbonate, 216 mM boric acid, and 108 mM potassium sulfate, and adjust to a pH of 10.0.

Hypochlorite Reagent— To 1 L of Alkaline Buffer, add 0.4 mL of sodium hypochlorite solution (10% chlorine concentration). [note—The hypochlorite solution is stable for 2 weeks.]

OPA Reagent— Transfer 2 g of N-acetyl-l-cysteine and 1.6 g of OPA to a 15-mL volumetric flask, dissolve in and dilute with alcohol to volume, and mix. Transfer this solution and 4 mL of 10% aqueous polyethylene (23) lauryl ether to a 1-L volumetric flask, dilute with 980 mL of Alkaline Buffer, and mix.

Chromatographic System— The liquid chromatograph is equipped with a fluorometric detector set to an excitation wavelength of 348 nm and an emission wavelength of 450 nm and a 4.0-mm × 150-mm column that contains 7.5-μm packing L17. The flow rate is about 0.3 mL per minute, and the column temperature is set at 50°. The system is programmed as follows. The column is equilibrated with Solution A; over the next 20 minutes, the composition of the Mobile Phase is changed linearly to 85% Solution A and 15% Solution B; then there is a step change to 40% Solution A and 60% Solution B; over the next 18 minutes, the composition is changed linearly to 100% Solution B and held for 7 minutes; then there is a step change to 100% Solution C, and this is held for 6 minutes; then there is a step change to Solution A, and this composition is maintained for the next 8 minutes.

Procedure and Postcolumn Reaction— Inject about 1.0 nmol of each amino acid under test into the chromatograph, and proceed as directed for Chromatographic System. As the effluent leaves the column, it is mixed with the Hypochlorite Reagent. The mixture passes through the first postcolumn reactor which consists of stainless steel 0.5-mm × 2-m tubing. A second postcolumn reactor of similar design is placed immediately downstream from the first postcolumn reactor and is used for the OPA postcolumn reaction. The flow rates for both the Hypochlorite Reagent and the OPA Reagent are 0.2 mL per minute, resulting in a total flow rate (i.e., Hypochlorite Reagent, OPA Reagent, and column effluent) of 0.7 mL per minute exiting from the postcolumn reactors. Postcolumn reactions are conducted at 55°. This results in a residence time of about 33 seconds in the OPA postcolumn reactor. After postcolumn derivatization, the column effluent passes through the fluorometric detector.

#### Method 3—Precolumn Determination

Precolumn derivatization of amino acids with phenylisothiocyanate (PITC) followed by reverse-phase HPLC separation with UV detection is used.

PITC reacts with amino acids to form phenylthiocarbamyl (PTC) derivatives, which can be detected with high sensitivity at 254 nm. Therefore, precolumn derivatization of amino acids with PITC followed by a reverse-phase HPLC separation with UV detection is used to analyze the amino acid composition.

After the reagent is removed under vacuum, the derivatized amino acids can be stored dry and frozen for several weeks with no significant degradation. If the solution for injection is kept cold, no noticeable loss in chromatographic response occurs after three days.

Separation of the PTC-amino acids on a reverse-phase HPLC with ODS column is accomplished through a combination of changes in concentrations of acetonitrile and buffer ionic strength. PTC-amino acids eluted from the column are monitored at 254 nm.

The detection limit is considered to be 1 pmol for most of the amino acid derivatives. Response linearity is obtained in the range of 20 to 500 pmol with correlation coefficients exceeding 0.999. To obtain good compositional data, a sample larger than 500 ng of protein/peptide before hydrolysis is best suited for this amino analysis of proteins/peptides.

One method of precolumn PITC derivatization is described below.

#### Mobile Phase Preparation—

Solution A: 0.05 M ammonium acetate, adjusted with phosphoric acid to a pH of 6.8.

Solution B— Prepare 0.1 M ammonium acetate, adjust with phosphoric acid to a pH of 6.8, and then prepare a mixture of this solution and acetonitrile (1:1).

Solution C: a mixture of acetonitrile and water (70:30).

Mobile Phase— Use variable mixtures of Solution A, Solution B, and Solution C as directed for Chromatographic System.

#### Derivatization Reagent Preparation—

Coupling Buffer: a mixture of acetonitrile, pyridine, triethylamine, and water (10:5:2:3).

Sample Solvent: a mixture of water and acetonitrile (7:2).

Sample Derivatization Procedure— Dissolve the lyophilized test sample in 100 μL of the Coupling Buffer, and then dry in a vacuum centrifuge to remove any hydrochloride if a protein hydrolysis step was used. Dissolve the test sample in 100 μL of Coupling Buffer, add 5 μL of PITC, and incubate at room temperature for 5 minutes. The test sample is again dried in a vacuum centrifuge, and is dissolved in 250 μL of Sample Solvent.

...omatographic System— The liquid chromatograph is equipped with a 254-nm detector and a 4.6-mm × 250-mm column that contains 5-μm packing L1. The flow rate is about 1 mL per minute, and the column temperature is maintained at 52°. The system is programmed as follows. The column is equilibrated with Solution A; over the next 15 minutes, the composition of the Mobile Phase is changed linearly to 85% Solution A and 15% Solution B; over the next 15 minutes, the composition is changed linearly to 50% Solution A and 50% Solution B; then there is a step change to 100% Solution C, and this is held for 10 minutes; then there is a step change to 100% Solution A, and the column is allowed to equilibrate before the next injection.

Procedure— Inject about 1.0 nmol of each PITC-amino acid under test (10-μL sample in Sample Solvent) into the chromatograph, and proceed as directed for Chromatographic System.

#### Method 4—Precolumn AQC Derivatization

Precolumn derivatization of amino acids with 6-aminoquinolyl-N-hydroxysuccinimidyl carbamate (AQC) followed by reverse-phase HPLC separation with fluorometric detection is used.

AQC reacts with amino acids to form stable, fluorescent unsymmetric urea derivatives (AQC-amino acids) which are readily amenable to analysis by reverse-phase HPLC. Therefore, precolumn derivatization of amino acids with AQC followed by reverse-phase HPLC separation is used to analyze the amino acid composition.

Separation of the AQC-amino acids on an ODS column is accomplished through a combination of changes in the concentrations of acetonitrile and salt. Selective fluorescence detection of the derivatives with an excitation wavelength at 250 nm and an emission wavelength at 395 nm allows for the direct injection of the reaction mixture with no significant interference from the only major fluorescent reagent byproduct, 6-aminoquinoline. Excess reagent is rapidly hydrolyzed ( $t_{1/2} < 15$  seconds) to yield 6-aminoquinoline-N-hydroxysuccinimide and carbon dioxide, and after 1 minute no further derivatization can take place.

Peak areas for AQC-amino acids are essentially unchanged for at least 1 week at room temperature, and the derivatives have more than sufficient stability to allow for overnight automated chromatographic analysis.

The detection limit is considered to be ranging from about 40 fmol to 320 fmol for each amino acid, except for Cys. The detection limit for Cys is approximately 800 fmol. Response linearity is obtained in the range of 2.5 μM to 200 μM with correlation coefficients exceeding 0.999. Good compositional data can be obtained from the analysis of derivatized protein hydrolysates containing as little as 30 ng of protein/peptide.

One method of precolumn AQC derivatization is shown below.

#### Mobile Phase Preparation—

Solution A— Prepare a solution having a composition of 140 mM sodium acetate and 17 mM triethylamine, and adjust with phosphoric acid to a pH of 5.02.

Solution B: a mixture of acetonitrile and water (60:40).

Mobile Phase— Use variable mixtures of Solution A and Solution B as directed for Chromatographic System.

Sample Derivatization Procedure— Dissolve about 2 μg of the test sample in 20 μL of 15 mM hydrochloric acid, and dilute with 0.2 M borate buffer (pH 8.8) to 80 μL. The derivatization is initiated by the addition of 20 μL of 10 mM AQC in acetonitrile, and allowed to proceed for 10 minutes at room temperature.

Chromatographic System— The liquid chromatograph is equipped with a fluorometric detector set at an excitation wavelength of 250 nm and an emission wavelength of 395 nm and a 3.9-mm × 150-mm column that contains 4-μm packing L1. The flow rate is about 1 mL per minute, and the column temperature is maintained at 37°. The system is programmed as follows. The column is equilibrated with Solution A; over the next 0.5 minute, the composition of the Mobile Phase is changed linearly to 98% Solution A and 2% Solution B; then over the next 14.5 minutes to 93% Solution A and 7% Solution B; then over the next 4 minutes to 87% Solution A and 13% Solution B; over the next 14 minutes to 68% Solution A and 32% Solution B; then there is a step change to 100% Solution B for a 5-minute wash; over the next 10 minutes, there is a step change to 100% Solution A; and the column is allowed to equilibrate before the next injection.

Procedure— Inject about 0.05 nmol of each AQC-amino acid under test into the chromatograph, and proceed as directed for Chromatographic System.

#### Method 5—Precolumn OPA Derivatization

Precolumn derivatization of amino acids with OPA followed by reverse-phase HPLC separation with fluorometric detection is used. This technique does not detect amino acids that exist as secondary amines (e.g., proline).

OPA in conjunction with a thiol reagent reacts with primary amine groups to form highly fluorescent isoindole products. 2-Mercaptoethanol and 3-mercaptopropionic acid can be used as thiol. OPA itself does not fluoresce and consequently produces no interfering peaks. In addition, its solubility and stability in aqueous solution, along with the rapid kinetics for the reactions, make it amenable to automated derivatization and analysis using an autosampler to mix the sample with the reagent. However, lack of reactivity with secondary amino acids has been a predominant drawback. This method does not detect amino acids that exist as secondary amines (e.g., proline). To compensate for this drawback, this technique may be combined with another technique described in Method 7 or Method 8.

Precolumn derivatization of amino acids with OPA is followed by reverse-phase HPLC separation. Because of the instability of the OPA-amino acid derivative, HPLC separation and analysis are performed immediately following derivatization. The liquid chromatograph is equipped with a fluorometric detector for the detection of derivatized amino acids.

Fluorescence intensity of the OPA-derivatized amino acids are monitored with an excitation wavelength of 348 nm and an emission wavelength of 450 nm.

The detection limits as low as 50 fmol via fluorescence have been reported, although the practical limit of analysis remains at 1 pmol. One method of precolumn OPA derivatization is shown below.

#### Mobile Phase Preparation—

Solution A: a mixture of 100 mM sodium acetate (pH 7.2), methanol, and tetrahydrofuran (900:95:5).

Solution B: methanol.

Mobile Phase— Use variable mixtures of Solution A and Solution B as directed for Chromatographic System.

Derivatization Reagent— Dissolve 50 mg of OPA in 1.25 mL of methanol (protein sequencing grade). Add 50 μL of 2-mercaptoethanol and 11.2 mL of 0.4 M sodium borate (pH 9.5), and mix. [note—This reagent is stable for 1 week.]

Sample Derivatization Procedure— Transfer about 5 μL of the test sample to an appropriate container, add 5 μL of the Derivatization Reagent, and mix. After 1 minute, add not less than 20 μL of 0.1 M sodium acetate (pH 7.0). Use 20 μL of this solution for analysis. [note—Use of an internal standard (e.g., norleucine) is recommended for quantitative analysis because of potential reagent volume variations in the sample derivatization. The sample derivatization is performed in an automated on-line fashion. Because of the instability of the OPA-amino acid derivative, HPLC separation and analysis are performed immediately following derivatization.]

Chromatographic System— The liquid chromatograph is equipped with a fluorometric detector set at an excitation wavelength of 348 nm and an emission wavelength of 450 nm and a 4.6-mm × 75-mm column that contains 3-μm packing L3. The flow rate is about 1.7 mL per minute, and the column temperature is maintained at 37°. The system is programmed as follows. The column is equilibrated with 92% Solution A and 8% Solution B; over the next 2 minutes, the composition of the Mobile Phase is changed to 83% Solution A and 17% Solution B, and held for an additional 3 minutes; then changed to 54% Solution A and 46% Solution B over the next 5 minutes, and held for an additional 2 minutes; then changed to 34% Solution A and 66% Solution B over the next 2 minutes, and held for 1 minute; then over the next 0.3 minute changed to 20% Solution A and 80% Solution B, and held for an additional 2.6 minutes; and then finally over 0.6 minute changed to 92% Solution A and 8% Solution B, and held for an additional 0.6 minute.

Procedure— Inject about 0.02 nmol of each OPA-amino acid under test into the chromatograph, and proceed as directed for Chromatographic System.

#### Method 6—Postcolumn DABS-Cl Derivatization

Precolumn derivatization of amino acids with (dimethylamino)azobenzenesulfonyl chloride (DABS-Cl) followed by reverse-phase HPLC separation with visible light detection is used.

DABS-Cl is a chromophoric reagent employed for the labeling of amino acids. Amino acids labeled with DABS-Cl (DABS-amino acids) are highly stable and show the maximum absorption at 436 nm.

DABS-amino acids, all 19 naturally occurring amino acids derivatives, can be separated on an ODS column of a reverse-phase HPLC by employing gradient systems consisting of acetonitrile and aqueous buffer mixture. Separated DABS-amino acids eluted from the column are detected at 436 nm in the visible region.

This method can analyze the imino acids, such as proline, together with the amino acids, at the same degree of sensitivity. DABS-Cl derivatization method permits the simultaneous quantification of tryptophan residues by previous hydrolysis of the protein/peptide with sulfonic acids, such as mercaptoethanesulfonic acid, p-toluenesulfonic acid, or methanesulfonic acid, described for Method 2 in Protein Hydrolysis under Amino Acid Analysis. The other acid-labile residues, asparagine and glutamine, can also be analyzed by previous conversion into diaminopropionic acid and diaminobutyric acid, respectively, by treatment of protein/peptide with BTI, described for Method 11 in Protein Hydrolysis under Amino Acid Analysis.

The nonproteinogenic amino acid, norleucine, cannot be used as an internal standard in this method as this compound is eluted in a chromatographic region crowded with peaks of primary amino acids. Nitrotyrosine can be used as an internal standard because it is eluted in a clean region.

The detection limit of DABS-amino acid is about 1 pmol. As little as 2 to 5 pmol of an individual DABS-amino acid can be quantitatively analyzed with reliability, and only 10 ng to 30 ng of the dabsylated protein hydrolysate is required for each analysis.

One method for precolumn DABS-Cl derivatization is shown below.

Mobile Phase Preparation—

Solution A: 25 mM sodium acetate (pH 6.5) containing 4% of dimethylformamide.

Solution B: acetonitrile.

Mobile Phase— Use variable mixtures of Solution A and Solution B as directed for Chromatographic System.

Derivatization Reagent Preparation—

Sample Buffer: 50 mM sodium bicarbonate, adjusted to a pH of 8.1.

Derivatization Reagent— Dissolve 1.3 mg of DABS-Cl in 1 mL of acetonitrile. [note—This reagent is prepared fresh shortly before the derivatization step.]

Sample Dilution Buffer— Prepare a mixture of 50 mM sodium phosphate (pH 7.0) and alcohol (1:1).

Sample Derivatization Procedure— Dissolve the test sample in 20  $\mu$ L of Sample Buffer, add 40  $\mu$ L of Derivatization Reagent, and mix. The sample container is sealed with a silicon-rubber stopper, and heated to 70° for 10 minutes. During the sample heating, the mixture will become completely soluble. After the derivatization, dilute the test sample with an appropriate quantity of the Sample Dilution Buffer.

Chromatographic System— The liquid chromatograph is equipped with a 436-nm detector and a 4.6-mm  $\times$  250-mm column that contains packing L1. The flow rate is about 1 mL per minute, and the column temperature is maintained at 40°. The system is programmed as follows. The column is equilibrated with 85% Solution A and 15% Solution B; over the next 20 minutes, the composition of the Mobile Phase is changed to 60% Solution A and 40% Solution B; over the next 12 minutes, the composition is changed to 30% Solution A and 70% Solution B, and held for an additional 2 minutes.

Procedure— Inject about 0.05 nmol of the DABS-amino acids into the chromatograph, and proceed as directed for Chromatographic System.

Method 7—Precolumn FMOC-Cl Derivatization

Precolumn derivatization of amino acids with 9-fluorenylmethyl chloroformate (FMOC-Cl) followed by reverse-phase HPLC separation with fluorometric detection is used.

FMOC-Cl reacts with both primary and secondary amino acids to form highly fluorescent products. The reaction of FMOC-Cl with amino acid proceeds under mild conditions, in aqueous solution, and is completed in 30 seconds. The derivatives are stable, with only the histidine derivative showing any breakdown. Although FMOC-Cl is fluorescent itself, the reagent excess and fluorescent side-products can be eliminated without loss of FMOC-amino acids.

FMOC-amino acids are separated by reverse-phase HPLC using an ODS column. The separation is carried out by gradient elution varied linearly from a mixture of acetic acid buffer, methanol, and acetonitrile (50:40:10) to a mixture of acetonitrile and acetic acid buffer (50:50), and 20 amino acid derivatives that are separated in 20 minutes. Each derivative eluted from the column is monitored by a fluorometric detector set at an excitation wavelength of 260 nm and an emission wavelength of 313 nm.

The detection limit is in the low fmol range. A linearity range of 0.1  $\mu$ M to 50  $\mu$ M is obtained for most amino acids.

One method for precolumn FMOC-Cl derivatization is shown below.

Mobile Phase Preparation—

Acetic Acid Buffer— Transfer 3 mL of glacial acetic acid and 1 mL of triethylamine to a 1-L volumetric flask, and dilute with HPLC grade water to volume. Adjust with sodium hydroxide to a pH of 4.20.

Solution A: a mixture of Acetic Acid Buffer, methanol, and acetonitrile (50:40:10).

Solution B: a mixture of acetonitrile and Acetic Acid Buffer (50:50).

Mobile Phase— Use variable mixtures of Solution A and Solution B as directed for Chromatographic System.

Derivatization Reagent Preparation—

Borate Buffer— Prepare a 1 M boric acid solution, and adjust with sodium hydroxide to a pH of 6.2.

FMOC-Cl Reagent— Dissolve 155 mg of 9-fluorenylmethyl chloroformate in 40 mL of acetone, and mix.

Sample Derivatization Procedure— To 0.4 mL of the test sample add 0.1 mL of Borate Buffer and 0.5 mL of FMOC-Cl Reagent. After about 40 seconds, extract the mixture with 2 mL of pentane, and then extract again with fresh pentane. The aqueous solution with amino acid derivatives is then ready for injection.

Chromatographic System— The liquid chromatograph is equipped with a fluorometric detector set at an excitation wavelength of 260 nm and an emission wavelength of 313 nm and a 4.6-mm  $\times$  125-mm column that contains 3- $\mu$ m packing L1. The flow rate is about 1.3 mL per minute. The system is programmed as follows. The column is equilibrated with Solution A, and this composition is maintained for 3 minutes; over the next 9 minutes, it is changed to 100% Solution B; then over the next 0.5 minute, the flow rate is increased to 2 mL per minute, and held until the final FMOC-amino acid is eluted from the column. The total run time is about 20 minutes.

Procedure— Inject not less than 0.01 nmol of each FMOC-amino acid under test into the chromatograph, and proceed as directed for Chromatographic System. The FMOC-histidine derivative will generally give a lower response than the other derivatives.

Method 8—Precolumn NBD-F Derivatization

Precolumn derivatization of amino acids with 7-fluoro-4-nitrobenzo-2-oxa-1,3-diazole (NBD-F) followed by reverse-phase HPLC separation with fluorometric detection is used.

7-Fluoro-4-nitrobenzo-2-oxa-1,3-diazole (NBD-F) reacts with both primary and secondary amino acids to form highly fluorescent products. Amino acids are derivatized with NBD-F by heating to 60° for 5 minutes.

NBD-amino acid derivatives are separated on an ODS column of reverse-phase HPLC by employing a gradient elution system consisting of acetonitrile and aqueous buffer mixture, and 17 amino acid derivatives that are separated in 35 minutes. E-aminocaproic acid can be used as an internal standard because it is eluted in a clean chromatographic region. Each derivative eluted from the column is monitored by a fluorometric detector set at an excitation wavelength of 480 nm and an emission wavelength of 530 nm.

The sensitivity of this method is almost the same as that for the precolumn OPA derivatization method (Method 5), excluding proline to which OPA is not reactive and might be advantageous for NBD-F against OPA.

The detection limit for each amino acid is about 10 fmol. Profile analysis was achieved for about 1.5 mg of protein hydrolysates in the final precolumn labeling reaction mixture for HPLC.

One method for precolumn NBD-F derivatization is shown below.

Mobile Phase Preparation—

Solution A: a solution of 10mM sodium citrate containing 75 mM sodium perchlorate, adjusted with hydrochloric acid to a pH of 6.2.

Solution B: a mixture of acetonitrile and water (50:50).

Derivatization Reagent Preparation—

Sample Buffer: a 0.1 M boric acid solution, adjusted with sodium hydroxide to a pH of 9.2.

Derivatization Reagent— Dissolve 5 mg of NBD-F in 1.0 mL of alcohol, and mix.

Sample Derivatization Procedure— Dissolve the test sample in 20  $\mu$ L of Sample buffer, add 10  $\mu$ L of Derivatization Reagent, and mix. The sample container is heated at 60° for 5 minutes. After the derivatization, dilute the test sample with 300  $\mu$ L of Solution A.

Chromatographic System— The liquid chromatograph is equipped with a fluorometric detector set at an excitation wavelength of 480 nm and an emission wavelength of 530 nm and a 4.6-mm  $\times$  150-mm column that contains 5- $\mu$ m particle size ODS silica packing. The flow rate is about 1.0 mL per minute, and the column temperature is maintained at 40°. The system is programmed as follows. The column is equilibrated with 94% Solution A and 6% Solution B; over the next 16 minutes, the composition is changed linearly to 63% Solution A and 37% Solution B; over the next 5 minutes, the composition is changed linearly to 62% Solution A and 38% Solution B; over the next 9 minutes, the composition is changed linearly to 100% Solution B, and held for an additional 5 minutes; then finally over 2 minutes, the composition is changed linearly to 94% Solution A and 6% Solution B; and then the column is allowed to equilibrate before the next injection.

Procedure— Inject about 15 pmol of each NBD-amino acid under test into the chromatograph, and proceed as directed for Chromatographic System.

DATA CALCULATION AND ANALYSIS

When determining the amino acid content of a protein/peptide hydrolysate, it should be noted that the acid hydrolysis step destroys tryptophan and cysteine. Serine and threonine are partially destroyed by acid hydrolysis, while isoleucine and valine residues may be only partially cleaved. Methionine can undergo oxidation during acid hydrolysis, and some amino acids (e.g., glycine and serine) are common contaminants. Application of adequate vacuum (less than 200  $\mu$ m of mercury or 26.7 Pa) or introduction of inert gas (argon) in the headspace of the reaction vessel during vapor phase hydrolysis can reduce the level of oxidative destruction. Therefore, the quantitative results obtained for cysteine, tryptophan, threonine, isoleucine, valine, methionine, glycine, and serine from a protein/peptide hydrolysate may be variable and may warrant further investigation and consideration.

Calculations

Amino Acid Mole Percent— This is the number of specific amino acid residues per 100 residues in a protein. This result may be useful for evaluating amino acid analysis data when the molecular weight of the protein/peptide under investigation is unknown. This information can be used to corroborate the identity of a protein and has other applications. Carefully identify and integrate the peaks obtained as directed for each Procedure. Calculate the mole percent for each amino acid present in the test sample by the formula:

$$100rU / r$$

in which rU is the peak response, in nmol, of the amino acid under test; and r is the sum of peak responses, in nmol, for all amino acids present in the test sample. Comparison of the mole percent of the amino acids under test to data from known proteins can help establish or corroborate the identity of the sample protein.

Unknown Protein Samples— This data analysis technique can be used to estimate the protein concentration of an unknown protein sample using the amino acid analysis data.

Calculate the mass, in  $\mu$ g, of each recovered amino acid by the formula:

$$mMW / 1000$$

in which m is the recovered quantity, in nmol, of the amino acid under test; and MW is the average molecular weight, in mg, for that amino acid, corrected for the weight of the water molecule that was eliminated during peptide bond formation. The sum of the masses of the recovered amino acids will give an estimate of the total mass of the protein analyzed after appropriate correction for partially and completely destroyed amino acids. If the molecular weight of the unknown protein is available (i.e., by SDS-PAGE analysis or mass spectroscopy), the amino acid composition of the unknown protein can be predicted. Calculate the number of residues of each amino acid by the formula:

$$m / (1000M / MW)$$

in which m is the recovered quantity, in nmol, of the amino acid under test; M is the total mass, in  $\mu$ g, of the protein; and MW is the molecular weight, in mg, of the unknown protein.

Known Protein Samples— This data analysis technique can be used to investigate the amino acid composition and protein concentration of a protein sample of known molecular weight and amino acid composition using the amino acid analysis data. When the composition of the protein being analyzed is known, one can exploit the fact that some amino acids are recovered well, while other amino acid recoveries may be compromised because of complete or partial destruction (e.g., tryptophan, cysteine, threonine, serine, methionine), incomplete bond cleavage (i.e., for isoleucine and valine), and free amino acid contamination (i.e., by glycine and serine).

Because those amino acids that are recovered best represent the protein, these amino acids are chosen to quantify the amount of protein. Well-recovered amino acids are, typically, aspartate-asparagine, glutamate-glutamine, alanine, leucine, phenylalanine, lysine, and arginine. This list can be modified based on experience with one's own analysis system. Divide the quantity, in nmol, of each of the well-recovered amino acids by the expected number of residues for that amino acid to obtain the protein content based on each well-recovered amino acid. Average the protein content results calculated. The protein content determined for each of the well-recovered amino acids should be evenly distributed about the mean.

Discard protein content values for those amino acids that have an unacceptable deviation from the mean. Typically, a greater than 5% variation from the mean is considered unacceptable, but this is arbitrary. Recalculate the mean protein content from the remaining values to obtain the protein content of the sample. Divide the content of each amino acid by the calculated mean protein content to determine the amino acid composition of the sample by analysis.

Calculate the relative compositional error, in percentage, by the formula:

$$100m / mS$$

in which m is the experimentally determined quantity, in nmol per amino acid residue, of the amino acid under test; and mS is the known residue value for that amino acid. The average relative compositional error is the average of the absolute values of the relative compositional errors of the individual amino acids, typically excluding tryptophan and cysteine from this calculation. The average relative compositional error can provide important information on the stability of analysis run over time. The agreement in the amino acid composition between the protein sample and the known composition can be used to corroborate the identity and purity of the protein in the sample.

\* Suitable standards may be obtained from NIST (Gaithersburg, MD), Beckman Instruments (Fullerton, CA), Sigma Chemical (St. Louis, MO), Pierce (Rockford, IL), or Agilent (Palo Alto, CA).

## 1053 BIOTECHNOLOGY-DERIVED ARTICLES—CAPILLARY ELECTROPHORESIS

This chapter provides guidance and procedures used for characterization of biotechnology-derived articles by capillary electrophoresis. This chapter is harmonized with the corresponding chapter in JP and EP. Other characterization tests, also harmonized, are shown in [Biotechnology-Derived Articles—Amino Acid Analysis](#) 1052, [Biotechnology-Derived Articles—Isoelectric Focusing](#) 1054, [Biotechnology-Derived Articles—Peptide Mapping](#) 1055, [Biotechnology-Derived Articles—Polyacrylamide Gel Electrophoresis](#) 1056, and [Biotechnology-Derived Articles—Total Protein Assay](#) 1057.

## INTRODUCTION

Capillary electrophoresis is a physical method of analysis based on the migration, inside a capillary, of charged analytes dissolved in an electrolyte solution under the influence of a direct-current electric field. In this section we are describing four capillary electrophoresis methods: Free Solution Capillary Electrophoresis, Capillary Gel Electrophoresis, Capillary Isoelectric Focusing, and Micellar Electrophoresis.

## GENERAL PRINCIPLE

The migration velocity of the analyte under an electric field of intensity (E) is determined by the electrophoretic mobility of the analyte and the electroosmotic mobility of the buffer inside the capillary. The electrophoretic mobility of a solute ( $\mu_{ep}$ ) depends on the characteristics of the solute (electrical charge, molecular size, and shape) and the characteristics of the buffer in which the migration takes place (type and ionic strength of the electrolyte, pH, viscosity, and additives). The electrophoretic velocity ( $V_{ep}$ ) of a solute, assuming a spherical shape, is as follows:

$$V_{ep} = \mu_{ep} E = \left( \frac{q}{6\pi\eta r} \right) \left( \frac{V}{L} \right)$$

in which  $q$  is the effective charge of the particle;  $\eta$  is the viscosity of the buffer;  $r$  is the size of the solute ion;  $V$  is the applied voltage; and  $L$  is the total length of the capillary.

When an electric field is applied through the capillary filled with buffer, a flow of solvent, called electroosmotic flow, is generated inside the capillary. Its velocity depends on the electroosmotic mobility ( $\mu_{eo}$ ), which in turn depends on the charge density on the capillary internal wall and the buffer characteristics. The electroosmotic velocity ( $V_{eo}$ ) is as follows:

$$V_{eo} = \mu_{eo} E = \left( \frac{\epsilon\zeta}{\eta} \right) \left( \frac{V}{L} \right)$$

in which  $\epsilon$  is the dielectric constant of the buffer;  $\zeta$  is the zeta potential of the capillary surface; and the other terms are as defined above.

The electrophoretic and electroosmotic mobilities of the analyte may act in the same direction or in opposite directions, depending on the charge (positive or negative) of the solute, and the velocity of the solute ( $V$ ) is as follows:

$$V = V_{ep} \pm V_{eo}$$

The sum or the difference between the two velocities ( $V_{ep}$  and  $V_{eo}$ ) is used depending on whether the mobilities act in the same or opposite directions. Under conditions with a fast  $V_{eo}$ , with respect to the  $V_{ep}$  of the solutes, both negative and positive charged analytes can be separated in the same run. The time ( $t$ ) taken by the solute to migrate the distance ( $l$ ) from the injection end of the capillary to the detection point (capillary effective length) is as follows:

$$t = \frac{l}{V_{ep} \pm V_{eo}} = \frac{l(L)}{V(\mu_{ep} \pm \mu_{eo})}$$

in which the other terms are as defined above.

In general, the fused-silica capillaries used in electrophoresis bear negative charges on the inner wall, producing electroosmotic flow towards the cathode. The electroosmotic flow has to remain constant from run to run to obtain good reproducibility in the migration velocity of the solutes. For some applications, it might be necessary to reduce or suppress the electroosmotic flow by modifying the inner wall of the capillary or by changing the pH of the buffer solution.

When the sample is introduced in the capillary, each analyte ion of the sample migrates within the background electrolyte as an independent zone according to its electrophoretic mobility. The spreading of each solute band (zone dispersion) results from a different phenomena. Under ideal conditions, the sole contribution to the solute-zone broadening is molecular diffusion of the solute along the capillary (longitudinal diffusion). In this case, the efficiency of the zone is expressed as the number of theoretical plates ( $N$ ), as follows:

$$N = \frac{(\mu_{ep} \pm \mu_{eo})(Vl)}{2DL}$$

in which  $D$  is the molecular diffusion of the solute in the buffer; and the other terms are as defined above.

From a practical point of view, other phenomena, such as heat dissipation, sample adsorption onto the capillary wall, mismatched conductivity between sample and buffer, length of the injection plug, detector cell size, and unlevelled buffer reservoirs, can also significantly contribute to band dispersion. Separation between two bands (expressed by the resolution,  $RS$ ) can be achieved by modification of the electrophoretic mobility of the analytes, by the electroosmotic mobility induced by capillary, and by increasing the efficiency for the band of each analyte as follows:

$$R_s = \frac{\sqrt{N}(\mu_{epb} - \mu_{epa})}{4(\mu_{ep} \pm \mu_{eo})}$$

in which  $\mu_{epa}$  and  $\mu_{epb}$  are the electrophoretic mobilities of the two compounds to be separated;  $\mu_{ep}$  is the average electrophoretic mobility of the two solutes calculated as:

$$\mu_{ep} = \frac{1}{2} (\mu_{epb} + \mu_{epa})$$

and the other terms are as defined above.

#### APPARATUS

An apparatus for capillary electrophoresis is composed of a high voltage controllable power supply; two buffer reservoirs held at the same level and containing specified anodic and cathodic solutions; two electrodes assemblies (cathode and anode) immersed in the buffer reservoirs and connected to the power supply; a separation capillary usually made of fused-silica, sometimes with an optical viewing window aligned with the detector, depending on the detector, with the ends of the capillary placed in the buffer reservoirs and the capillary being filled with a solution specified in a given monograph; a suitable injection system; a detector capable of monitoring the amount of substance of interest passing through a segment of the separation capillary at a given time, generally based on absorption spectrophotometry (UV and visible), fluorimetry, conductimetric, amperometric, or mass spectrometric detection, depending on the specific applications, or even indirect detection to detect non-UV-absorbing and nonfluorescent compounds; and a thermostatic system capable of maintaining the temperature inside the capillary.

The method of injection of samples and its automation is critical for precise quantitative analysis. Methods of injection include gravity, pressure or vacuum, or electrokinetic injection. The amount of each sample component introduced electrokinetically depends on its electrophoretic mobility, thus possibly biasing the results.

It is expected that the capillary, the buffer solutions, the preconditioning method, the sample solution, and the migration conditions will be specified in the individual monograph. The electrolytic solution employed may be filtered to remove particles and degassed to avoid bubble formation that could interfere with the detection system. To achieve reproducible migration time of the solutes, it would be necessary to develop, for each analytical method, a rigorous rinsing routine after each injection.

#### FREE SOLUTION CAPILLARY ELECTROPHORESIS

In free solution capillary electrophoresis, analytes are separated in a capillary containing only buffer without any anticonvective medium. In this technique, separation takes place because the different components of the sample migrate as discrete bands with different velocities. The velocity of each band depends on the electrophoretic mobility of the solute and the electroosmotic flow on the capillary. Coated capillaries, with reduced electroosmotic flow, can be used to increase the separation capacity of those substances absorbing on fused-silica surfaces.

This mode of capillary electrophoresis is appropriate for the analysis of small (MW < 2000) and large (2000 < MW < 100,000) molecules. Due to the high efficiency achieved, molecules having only minute differences in their charge-to-mass ratio can be separated. This method also allows the separation of chiral compounds by adding chiral selectors to the separation buffer. The optimization of the separations requires consideration of a number of instrumental and electrolytic solution parameters.

##### Instrumental Parameters

**Voltage**— The separation time is universally proportional to applied voltage. However, an increase in the voltage used can cause excessive heat production, giving rise to temperature and viscosity gradients in the buffer inside the capillary, which causes band broadening and decreases resolution.

**Temperature**— The main effect of temperature is observed on buffer viscosity and electrical conductivity, thus affecting migration velocity. In some cases, an increase in capillary temperature can cause a conformational change of some proteins, modifying their migration time and the efficiency of the separation.

**Capillary**— The length and internal diameter of the capillary affects the analysis time, the efficiency of separations, and the load capacity. Increasing both effective length and total length can decrease the electric fields, at a constant voltage, which will increase migration time. For a given buffer and electric field, heat dissipation (thus, sample band broadening) depends on the internal diameter of the capillary. The latter also affects the detection limit, depending on the sample volume injected into the capillary and the detection system used.

The adsorption of sample components on the capillary wall limits efficiency; therefore, methods to avoid these interactions should be considered in the development of a separation method. This is critical in samples containing proteins. Strategies have been devised to avoid adsorption of proteins on the capillary wall. These strategies include both the use of extreme pH and the absorption of positively charged buffer additives that only require modification of the buffer composition. Other strategies include the coating of the internal wall of the capillary with a polymer covalently bonded to the silica that prevents interaction between the proteins and the negatively charged silica surface. Capillaries with coatings consisting of neutral-hydrophilic, cationic, and anionic polymers are commercially available.

##### Electrolytic Solution Parameters

**Buffer Type and Concentrations**— Suitable buffers for capillary electrophoresis have an appropriate buffer capacity in the pH range of choice and low mobility to minimize current generation.

To minimize peak shape distortion, it is important to match buffer-ion mobility to solute mobility whenever possible. The type of sample solvent used is important to achieve on-column sample focusing, which increases separation efficiency and improves detection. Also, an increase in buffer concentration at a given pH will decrease electroosmotic flow and solute velocity.

**Buffer pH**— The pH of the buffer can affect separation by modifying the charge of the analyte or other additives and by changing the electroosmotic flow. For protein and peptide separation, a change in the pH of the buffer from above the isoelectric point to below the isoelectric point changes the net charge of the solute from negative to positive. An increase in the buffer pH generally increases the electroosmotic flow.

**Organic Solvents**— Organic modifiers, such as methanol, acetonitrile, and others, are added to the aqueous buffer to increase the solubility of the solute or other additives and/or to affect the ionization degree of the sample components. The addition of these organic modifiers to the buffer generally causes a decrease in the electroosmotic flow.

**Additives for Chiral Separations**— To separate optical isomers, a chiral selector is added to the separation buffer. The most commonly used chiral selectors are cyclodextrins, although in some cases crown ethers, certain polysaccharides, or even proteins can be used. Because chiral recognition is governed by the different interactions between the chiral selector and each of the enantiomers, the resolution achieved for the chiral compounds depends largely on the type of chiral selector used. While developing a given separation it may be useful to test cyclodextrins having a different cavity size ( $\alpha$ ,  $\beta$ , or  $\gamma$ -cyclodextrin) or modified cyclodextrins with neutral (methyl, ethyl, hydroxyalkyl, etc.) or ionizable (aminomethyl, carboxymethyl, sulfobutylether, etc.) moieties. The resolution of chiral separations is also controlled by the concentration of the chiral selector, the composition and pH of the buffer, and the separation temperature. Organic additives, such as methanol or urea, can also affect the resolution of separation.

#### CAPILLARY GEL ELECTROPHORESIS

Separation takes place inside a capillary filled with a polymer acting as a molecular sieve. The smaller components in the sample move faster along the capillary than the larger ones. This method can be used for separation of biopolymers-proteins and DNA fragments, according to their molecular mass.

##### Characteristics of Chemical and Physical Gels

**Chemical Gels**— Chemical gels are prepared inside the capillary by reaction of monomers. One example of such a gel is a cross-linked polyacrylamide. This type of gel is bonded to

the fused-silica wall and cannot be removed without destroying the capillary. For protein analysis, the separation buffer usually contains sodium dodecyl sulfate, and the sample is denatured by heating in a mixture of sodium dodecyl sulfate and 2-mercaptoethanol or dithiothreitol before injection. Optimization of separation in a cross-linked gel is obtained by modifying the separation buffer (see Free Solution Capillary Electrophoresis) and by controlling the gel porosity during the gel preparation. For a cross-linked polyacrylamide gel, the porosity can be modified by changing the concentration of acrylamide and/or the ratio of the cross-linker. As a rule, a decrease in the porosity of the gel leads to a decrease in the mobility of the solutes. Due to the rigidity of this type of gel, only electrokinetic injection can be used.

**Physical Gels**— Physical gels are hydrophilic polymers (i.e., linear polyacrylamide, cellulose derivatives, dextran, etc.) which can be dissolved in aqueous separation buffers, giving rise to a separation medium that also acts as a molecular sieve. These polymeric separation media are easier to prepare than cross-linked polymers. They can be prepared in a vial and filled by pressure in a wall-coated capillary with no electroosmotic flow. Replacing the gel before every injection generally improves the separation reproducibility. The porosity of the physical gels can be increased by using polymers of higher molecular weight (at a given polymer concentration) or by decreasing the polymer concentration (for a given polymer molecular weight). A decrease in gel porosity leads to a decrease in the mobility of the solute for the same buffer. Both hydrodynamic and electromigration injection techniques can be used because the dissolution of these polymers in the buffer gives low viscosity solutions.

#### CAPILLARY ISOELECTRIC FOCUSING

The molecules migrate under the influence of the electric field, so long as they are charged, in a pH gradient generated by ampholytes having *pI* values in a wide range (poly-aminocarboxylic acids) dissolved in the separation buffer. The three basic steps in capillary isoelectric focusing are loading, focusing, and mobilization.

##### Loading—

**Loading in One Step**— The sample is mixed with ampholytes and introduced into the capillary by pressure or vacuum.

**Sequential Loading**— A leading buffer, then the ampholytes, then the sample mixed with ampholytes, again ampholytes alone, and finally the terminating buffer are introduced into the capillary. The volume of the sample must be small enough so as to not modify the pH gradient.

**Focusing**— When the voltage is applied, ampholytes migrate toward the cathode or the anode according to their net charge, creating the pH gradient from anode (lower pH) to cathode (higher pH). The components to be separated migrate until they reach a pH corresponding to their isoelectric point, and the current drops to very low values.

**Mobilization**— The bands of separated components migrate past the detector by one of the three following methods.

**Method 1**— During Focusing, under the influence of the electroosmotic flow when this flow is small enough to allow the focusing of the components.

**Method 2**— By application of positive pressure after Focusing.

**Method 3**— After Focusing, by adding salts in the cathode reservoir or the anode reservoir, depending on the direction chosen for mobilization, in order to alter the pH in the capillary when the voltage is applied. As the pH is changed, the proteins and ampholytes are mobilized in the direction of the reservoir, which contains added salts and pass the detector.

The separation achieved is expressed as  $\Delta pI$  and depends on the pH gradient ( $d\text{pH}$ ), the number of ampholytes having different *pI* values, the diffusion coefficient (D), the intensity of the electric field (E), and the variation of the electrophoretic mobility of the analyte with the pH, and is as follows:

$$\Delta pI = 3 \sqrt{\frac{D(d\text{pH} / dx)}{E(-d\mu / d\text{pH})}}$$

in which  $d\text{pH}/dx$  is the pH gradient; and  $-d\mu/d\text{pH}$  is the variation of the solution mobility with the pH in the region close to the *pI*.

**Optimization Parameters**— The major parameters that need to be considered in the development of separations are voltage, capillary, and solutes.

**Voltage**: use of high fields from 300 V/cm to 1,000 V/cm during Focusing.

**Capillary**— Depending on the Mobilization strategy selected (see above), the electroosmotic flow must be reduced or suppressed. Coated capillaries tend to reduce the electroosmotic flow.

**Solutions**— The anode buffer reservoir is filled with a solution of a lower pH than the *pI* of the most acidic ampholyte, and the cathode reservoir is filled with a solution with a higher pH than the *pI* of the most basic ampholyte. Phosphoric acid for the anode and sodium hydroxide for the cathode are frequently used.

Addition of a polymer, like methylcellulose, in the ampholyte solution tends to suppress convective forces (if any) and electroosmotic flow by increasing the viscosity. Commercial ampholytes covering many pH ranges are available and may also be mixed to obtain an expanded pH range. Broad pH ranges are used to estimate the isoelectric point, whereas narrower ranges are employed to improve accuracy. Calibration can be made by correlating migration time with the isoelectric point of a series of standard protein markers. During Focusing, precipitation of proteins at their isoelectric point can be prevented, if necessary, using buffer additives such as glycerol, surfactants, urea, or Zwitterionic buffers. However, depending on the concentration, urea can denature proteins.

#### MICELLAR ELECTROKINETIC CHROMATOGRAPHY (MEKC)

Separation takes place in an electrolytic solution that contains a surfactant, generally ionic, at a concentration above the critical micellar concentration. The solute molecules are distributed between the aqueous buffer and the pseudo-stationary phase composed by the micelles according to the solute's partition coefficient. The technique can be considered as a hybrid of electrophoresis and chromatography. It is an electrophoretic technique that can be used for the separation of both neutral and charged solutes maintaining the efficiency, speed, and instrumental suitability of capillary electrophoresis. One of the most widely used surfactants is sodium dodecyl sulfate, although other anionic and cationic surfactants, such as cetyl trimethyl ammonium salts, have also been used.

At neutral and alkaline pH, a strong electroosmotic flow is generated and moves the separation buffer ions in the direction of the cathode. If sodium dodecyl sulfate is used as surfactant, the electrophoretic migration of the anionic micelle is in the opposite direction, toward the anode. As a result, the overall micelle migration velocity is slowed compared to the bulk flow of the electrolytic solution. In the case of neutral solutes, because the analyte can partition between the micelle and the aqueous buffer and has no electrophoretic mobility, the analyte migration velocity will only depend on the partition coefficient between the micelle and the aqueous buffer. In the electropherogram, the peak corresponding to each uncharged solute is always between that of the electroosmotic flow marker and that of the micelle; and the time elapsed between these two peaks is called the separation window. For electrically charged solutes, the migration velocity depends on both the partition coefficient of the solute between the micelle and the aqueous buffer and on the electrophoretic mobility of the solute in the absence of micelles.

The separation mechanism is essentially chromatographic, and migration of the solute and resolution can be expressed in terms of the capacity factor of the solute ( $K'$ ), which is the ratio between the total number of moles of solute in the micelle to those in the mobile phase. For a neutral compound,  $K'$  is as follows:

$$K' = \frac{t_r - t_0}{t_0(1 - t_r/t_m)} = K \left( \frac{V_s}{V_m} \right)$$

in which  $t_r$  is the migration time of the solute;  $t_0$  is the analysis time of the unretained solute obtained by injecting an electroosmotic flow marker that does not enter the micelle (i.e., methanol);  $t_m$  is the micelle migration time measured by injecting a micelle marker, such as Sudan III, which migrates continuously associated in the micelle;  $K$  is the partition

coefficient of the solute; VS is the volume of the micelles phase; and VM is the volume of the mobile phase.

The resolution between two closely-migrating compounds (RS) is as follows:

$$R_s = \frac{\sqrt{N}}{4} \times \frac{\alpha-1}{\alpha} \times \frac{k_b}{k_b+1} \times \frac{1 - \left( \frac{t_0}{t_m} \right)}{1 + k_a \times \left( \frac{t_0}{t_m} \right)}$$

in which N is the number of theoretical plates for one of the compounds;  $\alpha$  is the selectivity obtained;  $k_a$  and  $k_b$  are retention factors for both components, respectively ( $k_b > k_a$ ); and the other terms are as defined above.

Similar, but not identical, equations give  $k$  and  $RS$  values for electrically charged compounds.

#### Optimization Parameters

The main parameters to be considered in the development of separations by MEKC are instrumental and electrolytic solution parameters.

##### Instrumental Parameters—

**Voltage**— Separation time is inversely proportional to applied voltage. An increase in voltage can cause excessive heat production that gives rise to temperature gradients and viscosity gradients of the buffer in the cross section of the capillary. This effect can be significant with high conductivity buffers, such as those containing micelles. Poor heat dissipation causes band broadening and decreases resolution.

**Temperature**— Variations in capillary temperature affect the partition coefficient of the solute between the buffer and the micelle, the critical micelle concentration, and the viscosity of the buffer. These parameters contribute to the migration time of the solutes.

**Capillary**— Length and internal diameter contribute to analysis time and efficiency of separations. Increasing both effective length and total length can decrease the electrical fields, working at constant voltage, and will increase migration time and improve the separation efficiency. The internal diameter controls heat dissipation, at a given buffer and electrical field, and provides a broadening of the sample band.

##### Electrolytic Solution Parameters—

**Surfactant Type and Concentration**— The type of surfactant, as the stationary phase in chromatography, affects the resolution because it modifies separation selectively. The  $\log K'$  of a neutral compound increases linearly with the concentration of detergent in the mobile phase. When  $K'$  approaches the value of

$$\sqrt{t_m / t_a}$$

resolution in MEKC reaches a maximum. Modifying the concentration of surfactant in the mobile phase changes the resolution.

**Buffer pH**— pH does not modify the partition coefficient of non-ionized solutes, but it can modify the electroosmotic flow in uncoated capillaries. A decrease in the buffer pH decreases the electroosmotic flow and, therefore, increases the resolution of the neutral solutes, giving rise to longer analysis time.

**Organic Solvents**— To improve separation of hydrophobic compounds, organic modifiers (methanol, propanol, acetonitrile, etc.) can be added to the separation electrolytic solution. The addition of these modifiers generally decreases migration time and selectivity of the separation. The addition of organic modifiers affects micelle formation, thus, a given surfactant concentration can be used only with a certain percentage of organic modifier before the micelleization equilibrium is eliminated or adversely affected, resulting in the absence of micelles and, therefore, the absence of the partition mechanism of MEKC. The elimination of micelles in the presence of a high content of organic solvent does not always mean that the separation will no longer be possible, because, in some cases, the hydrophobic interaction between the ionic surfactant monomer and the neutral solutes form solvophobic complexes that can be separated electrophoretically.

**Additives for Chiral Separations**— A chiral selector is included in the micellar system, either covalently bound to the surfactant or added to the micellar separation electrolyte. Micelles that have a moiety with chiral discrimination properties include salts, N-dodecanoyl-L-amino acids, bile salts, etc. Chiral resolution can also be achieved using chiral discriminators, such as cyclodextrins, added to the electrolytic solutions that contain micellicized achiral surfactants.

**Other Additives**— Selectivity can be modified by adding chemicals to the buffer. Addition of several types of cyclodextrins to the buffer is also used to reduce the interaction of hydrophobic solutes with the micelle, increasing the selectivity for this type of compound. The addition of substances able to modify solute-micelle interactions by adsorption on the latter has been used to improve the selectivity of the separations in MEKC. These additives may consist of a second surfactant (ionic or non-ionic), which gives rise to mixed micelles, metallic cations that dissolve in the micelle and give co-ordination complexes with the solutes.

#### Quantitative Analysis

Peak areas must be divided by the corresponding migration time to give the corrected area in order to compensate for the shift in migration time from run to run, thus reducing the variation of the response. Dividing the peak areas by migration time will also compensate for the different responses of sample constituents with different migration times. Where an internal standard is used, check that no peak of the substance to be examined is masked by that of the internal standard.

**Calculations**— From the values obtained, calculate the content of a component or components being determined. When indicated, the percentage of one (or more) components of the sample to be examined is calculated by determining the areas of the peak(s) as a percentage of the total corrected areas of all the peaks, excluding those due to solvents or any added reagents. The use of an automatic integration system (integrator or data acquisition and processing system) is recommended.

#### CAPILLARY ELECTROPHORESIS SYSTEM SUITABILITY

The choice of suitability parameters to be used will depend on the type of capillary electrophoresis that is performed. These parameters are the capacity factor ( $K'$ ) used only for Micellar Electrokinetic Chromatography, the number of theoretical plates ( $n$ ), the symmetry factor ( $AS$ ), and the resolution ( $RS$ ). Note that in previous sections, the theoretical expressions for  $n$  and  $RS$  have been described, but more practical equations that allow for the determination of these suitability parameters using the electrophoretograms are described below.

The number of theoretical plates ( $n$ ) may be calculated from the formula:

$$n = 5.54 (t / b0.5)^2$$

in which  $t$  is the distance, in mm, along the baseline between the point of injection and the perpendicular dropped from the maximum of the peak in question; and  $b0.5$  is the peak

width, in mm, at half-height.

The resolution (RS) may be calculated from the formula:

$$RS = 1.18(t_b - t_a) / b0.5b + b0.5a$$

in which  $t_b$  and  $t_a$  are the distances, in mm, along the baseline between the point of injection and the perpendicular dropped from the maxima of two adjacent peaks ( $t_b > t_a$ ); and  $b0.5b$  and  $b0.5a$  are the peak widths, in mm, at half-height.

The resolution (RS) may also be calculated by measuring the height of the valley (c) between two partly resolved peaks in a standard preparation, the height of the smaller peak (d), and by specifying  $(c/d) \leq x$ , in which  $x$  is the limit indicated in the individual monograph.

The symmetry factor of a peak (AS) may be calculated using the formula:

$$AS = b0.05/2A$$

in which  $b0.05$  is the width of the peak at one-twentieth of the peak height; and  $A$  is the distance between the perpendicular dropped from the peak maximum and the leading edge of the peak at one-twentieth of the peak height.

Other system suitability parameters include tests for area repeatability (i.e., standard deviation of areas or of area/migration time) and tests for migration time repeatability (i.e., standard deviation of migration time). For migration time repeatability, it will be necessary to provide for a test to measure the suitability of the capillary washing procedures. To avoid the lack of repeatability of the migration time, an alternative practice is to use a migration time relative to an internal standard.

A test for the verification of the signal-to-noise ratio for a standard preparation or the determination of the limit of quantitation is a useful system suitability parameter. The detection limit and quantitation limit correspond to a signal-to-noise ratio greater than 3 and 10, respectively. The signal-to-noise ratio (S/N) is calculated as follows:

$$S/N = 2H/hn$$

in which  $H$  is the height of the peak corresponding to the component concerned in the electrophoretogram obtained with the specified reference solution; and  $hn$  is the absolute value of the largest noise fluctuation from the baseline in an electrophoretogram obtained after injection of a blank and observed over a distance equal to twenty times the width at the half-height of the peak in the electrophoretogram obtained with the reference solution, and situated equally around the place where this peak would be found.

#### 1054 BIOTECHNOLOGY-DERIVED ARTICLES—ISOELECTRIC FOCUSING

This chapter provides guidance and procedures used for the characterization of biotechnology-derived articles by isoelectric focusing. This chapter is harmonized with the corresponding chapters in JP and EP. Other characterization tests, also harmonized, are shown in the USP general information chapters [Biotechnology-Derived Articles—Amino Acid Analysis](#) [1052](#), [Biotechnology-Derived Articles—Capillary Electrophoresis](#) [1053](#), [Biotechnology-Derived Articles—Peptide Mapping](#) [1055](#), [Biotechnology-Derived Articles—Polyacrylamide Gel Electrophoresis](#) [1056](#), and [Biotechnology-Derived Articles—Total Protein Assay](#) [1057](#).

#### INTRODUCTION

Isoelectric focusing (IEF) is a method of electrophoresis that separates proteins according to their isoelectric points. Separation is carried out in a slab of polyacrylamide or agarose gel that contains a mixture of amphoteric electrolytes (ampholytes). When subjected to an electrical field, the ampholytes migrate in the gel to create a pH gradient. In some cases, gels containing an immobilized pH gradient, prepared by incorporating weak acids and bases to specific regions of the gel network during the preparation of the gel, are used. When the applied proteins reach the gel fraction that has a pH that is the same as their isoelectric point, their charge is neutralized and migration ceases. Gradients can be made over various ranges of pH, according to the mixture of ampholytes chosen.

#### GENERAL PRINCIPLES

When a protein is at the position of its isoelectric point, it has no net charge and cannot be moved in a gel matrix by the electric field. It may, however, move from that position by diffusion. The pH gradient forces a protein to remain in its isoelectric point position, thus concentrating it; this concentration effect is called “focusing”. Increasing the applied voltage or reducing the sample load results in improved resolution of bands. The applied voltage is limited by the heat generated because the heat must be dissipated. The use of thin gels and an efficient cooling plate controlled by a thermostatic circulator prevents the burning of the gel while allowing sharp focusing. The separation is estimated by determining the minimum pl difference, which is necessary to separate two neighboring bands, as follows:

$$\Delta pI = 3 \sqrt{\frac{D(dpH/dx)}{E(-d\mu/dpH)}}$$

in which  $D$  is the diffusion coefficient of the protein;  $dpH/dx$  is the pH gradient;  $E$  is the intensity of the electric field, in volts per centimeter; and  $-d\mu/dpH$  is the variation of the solute mobility with the pH in the region close to the pl. Because  $D$  and  $-d\mu/dpH$  for a given protein cannot be altered, the separation can be improved by using a narrower pH range and by increasing the intensity of the electric field.

From an operational point, special attention must be paid to sample characteristics and/or preparation. Salt in a sample can be problematic, and it is best to prepare the sample, if possible, in deionized water or 2% ampholytes using dialysis or gel filtration if necessary. Potentials of 2500 volts have been used and are considered optimal under a given set of conditions. Up to 30 watts of constant power can be applied and will generally give complete separation in 1.5 to 3.0 hours. The time required for completion of focusing in thin-layer polyacrylamide gels is determined by placing a colored protein (e.g., hemoglobin) at different positions on the gel surface and by applying the electric field: the steady state is reached when all applications give an identical band pattern. In some procedures the completion of the focusing is indicated by the time elapsed after the sample application.

Resolution between protein bands on an IEF gel prepared with carrier ampholytes can be quite good. Better resolution may be achieved by using immobilized pH gradients where the buffering species, which are analogous to carrier ampholytes, are copolymerized within the gel matrix. Proteins exhibiting pl values differing by as little as 0.02 pH units may be resolved using a gel prepared with carrier ampholytes, whereas immobilized pH gradients can resolve protein differing by approximately 0.001 pH units.

The IEF gel can be used as an identity test when migration on the gel is compared to a standard preparation and IEF calibration proteins; the IEF gel can be used as a limit test when the density of a band on IEF is compared subjectively with the density of bands appearing in a standard preparation, or it can be used as a semiquantitative test when the density is measured using a densitometer or similar instrumentation to determine the relative concentration of protein in the bands.

#### APPARATUS

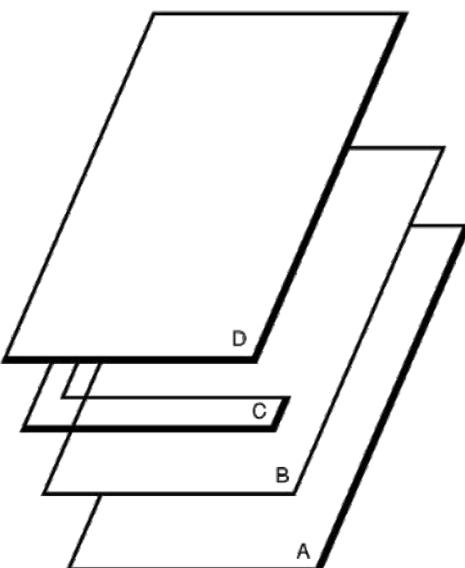

An apparatus for isoelectric focusing consists of a controllable direct current generator, of stabilized output; a rigid plastic isoelectric focusing chamber that contains a cooled plate of suitable material to support the gel; and a plastic cover with platinum electrodes that are connected to the gel by means of paper wicks of suitable width, length, and thickness, impregnated with solutions of anodic and cathodic electrolytes.

#### PROCEDURE

Unless otherwise indicated in a given monograph, the following procedure in thick polyacrylamide slab gels is to be used.

##### Preparation of the Gels

Assembly— Composed of a glass plate (A) on which a polyester film (B) is placed to facilitate handling of the gel, one or more spacers (C), a second glass plate (D), and clamps to hold the structure together (see [Figure 1](#)).

**Figure 1. Mould**

7.5% Polyacrylamide Gel— Dissolve 29.1 g of acrylamide and 0.9 g of methylenebisacrylamide in 100 mL of water. To 2.5 volumes of this solution, add the mixture of ampholytes specified in the individual monograph, and dilute up to 10 volumes with water. Mix carefully, and degas the solution.

Preparation of the Assembly— Place the polyester film on the lower glass plate, apply the spacer, place the second glass plate, and fit the clamps. Before use, place the mixture on a magnetic stirrer, and add 0.25 volumes of a 10% solution of ammonium persulfate and 0.25 volumes of tetramethylenediamine. Immediately fill the space between the glass plates of the assembly with the gel.

Fixing Solution for Isoelectric Focusing Polyacrylamide Gel— Mix 35 g of sulfosalicylic acid and 100 g of trichloroacetic acid in 1000 mL of water.

Coomassie Staining Solution and Destaining Solution— Use the same solutions indicated in general information chapter [Biotechnology-Derived Articles—Polyacrylamide Gel Electrophoresis](#) (1056).

Procedure— Dismantle the assembly, and using the polyester film, transfer the gel onto the cooled support wetted with a few mL of a suitable liquid, taking care to avoid forming air bubbles. Prepare the test solutions and reference solutions as specified in the individual monograph. Place strips of paper for sample application, about 10 mm × 5 mm in size, on the gel, and impregnate each with the prescribed amount of the test and reference solutions. If the protein concentration of the solution is too low, several strips may be superimposed (up to four). Also apply the prescribed quantity of a solution of proteins with known isoelectric points as pH markers to calibrate the gel. In some procedures, the gel has precast slots where a solution of the sample is applied instead of using impregnated paper strips. Cut two strips of paper to the length of the gel, and impregnate them with the electrolyte solutions: acid for the anode and alkaline for the cathode. The compositions of the anode and cathode solutions are given in the individual monograph. Apply these paper wicks to each side of the gel several mm from the edge. Fit the cover so that the electrodes are in contact with the wicks (with respect to the anodic and cathodic poles). Proceed with the isoelectric focusing by applying the electrical parameters described in the individual monograph. Switch off the current when the migration of the mixture of standard proteins has stabilized. Using forces, remove the sample application strips and the two electrode wicks. Immerse the gel in Fixing Solution for Isoelectric Focusing Polyacrylamide Gel. Incubate with gentle shaking at room temperature for 30 minutes. Drain off the solution, and add 200 mL of Destaining Solution. Incubate with shaking for 1 hour. Drain the gel, and add Coomassie Staining Solution. Incubate for 30 minutes. Destain the gel by passive diffusion with Destaining Solution until the bands are well visualized against a clear background. Locate the position and intensity of the bands in the electropherogram, as prescribed in the individual monograph.

Alternative Procedure— When a monograph references the general method for isoelectric focusing above, variations in methodology or procedure may be used, subject to validation. These variations include the use of commercially available precast gels; the use of immobilized pH gradients; the use of rod gels, and the use of cassettes of different dimensions, including ultrathin (0.2 mm) gels; variations in the sample application procedure, including different sample volumes or the use of sample application masks or wicks other than paper; the use of alternate running conditions, including variations in the electric field depending on gel dimensions and equipment, and the use of fixed migration times rather than subjective interpretation of band stability; the inclusion of a prefocusing step; the use of automated instrumentation; and the use of agarose gels.

##### Validation of Procedure

Where alternative methods to the general method are employed, they must be validated. The following criteria may be used to validate the separation: formation of a stable pH gradient of desired characteristics, evaluated using colored pH markers of known isoelectric points; comparison with the electropherogram provided with the chemical reference substance for the preparation to be examined; and any other validation criteria as prescribed in the individual monograph.

##### SPECIFIED VARIATIONS TO THE GENERAL METHOD

Variations to the general method required for the analysis of specific substances may be specified in detail in individual monographs. Variations may include the addition of urea in the running gel (a 3 M concentration is often satisfactory to keep the protein in solution, but up to 8 M can be used). Some proteins precipitate at their isoelectric point. In this case, urea is included in the gel formulation to keep the protein in solution. If urea is used, only fresh solutions should be used to prevent carbamylation of the protein. Other variations include the use of alternative staining methods and the use of gel additives such as nonionic detergents (e.g., octylglucoside) or zwitterionic detergents (e.g., CHAPS or CHAPSO) to prevent proteins from aggregating or precipitating.

note—The following are general precautionary items that can be used to improve the method.

- Samples can be applied to any area on the gel, but in general, they should be applied to areas where they are expected to focus. To protect the proteins from extreme pH environments, samples should not be applied close to either electrode. During method development, the analyst can try applying the protein in three positions on the gel (i.e., middle and both ends); the pattern of a protein applied at opposite ends of the gel may not be identical.
- A phenomenon known as cathodic drift, where the pH gradient decays over time, may occur if a gel is focused too long. Although not well understood, electroendoosmosis and absorption of carbon dioxide may be factors that lead to cathodic drift. Cathodic drift is observed as focused protein migrating off the cathode end of the gel. Immobilized pH gradients may be used to address this problem.
- Efficient cooling (approximately 4°) of the bed that the gel lies on during focusing is important. High field strengths used during isoelectric focusing can lead to overheating and affect the quality of the focused gel.

#### 1055 BIOTECHNOLOGY-DERIVED ARTICLES—PEPTIDE MAPPING

This chapter provides guidance and procedures used for characterization of biotechnology-derived articles by peptide mapping. This chapter is harmonized with the corresponding chapter in JP and EP. Other characterization tests, also harmonized, are shown in [Biotechnology-Derived Articles—Amino Acid Analysis](#) 1052, [Biotechnology-Derived Articles—Capillary Electrophoresis](#) 1053, [Biotechnology-Derived Articles—Isoelectric Focusing](#) 1054, [Biotechnology-Derived Articles—Polyacrylamide Gel Electrophoresis](#) 1056, and [Biotechnology-Derived Articles—Total Protein Assay](#) 1057.

#### INTRODUCTION

Peptide mapping is an identity test for proteins, especially those obtained by rDNA technology. It involves the chemical or enzymatic treatment of a protein, resulting in the formation of peptide fragments, followed by separation and identification of the resultant fragments in a reproducible manner. It is a powerful test that is capable of identifying single amino acid changes resulting from events such as errors in the reading of complementary DNA (cDNA) sequences or point mutations. Peptide mapping is a comparative procedure because the information obtained, compared to a reference standard or reference material similarly treated, confirms the primary structure of the protein, is capable of detecting whether alterations in structure have occurred, and demonstrates process consistency and genetic stability. Each protein presents unique characteristics that must be well understood so that the scientific and analytical approaches permit validated development of a peptide map that provides sufficient specificity.

This section provides detailed assistance in the application of peptide mapping and its validation to characterize the desired protein product, to evaluate the stability of the expression construct of cells used for recombinant DNA products, to evaluate the consistency of the overall process, and to assess product stability, as well as to ensure the identity of the protein product or to detect the presence of protein variant. The validation scheme presented differentiates between qualification of the method at an early stage in the regulatory process, the Investigational New Drug (IND) level, and full validation in support of New Drug Application (NDA), Product License Application (PLA), or Marketing Authorization Application (MAA).

The validation concepts described are consistent with the general information chapter [Validation of Compendial Procedures](#) 1225 and with the International Conference on Harmonization (ICH) document on Analytical Methods Validation.

#### THE PEPTIDE MAP

Peptide mapping is not a general method, but involves developing specific maps for each unique protein. Although the technology is evolving rapidly, there are certain methods that are generally accepted. Variations of these methods will be indicated, when appropriate, in specific monographs.

A peptide map may be viewed as a fingerprint of a protein and is the end product of several chemical processes that provide a comprehensive understanding of the protein being analyzed. Four major steps are necessary for the development of the procedure: isolation and purification of the protein, if the protein is part of a formulation; selective cleavage of the peptide bonds; chromatographic separation of the peptides; and analysis and identification of the peptides. A test sample is digested and assayed in parallel with a reference standard or reference material. Complete cleavage is more likely to occur when enzymes such as endoproteases (e.g., trypsin) are used instead of chemical cleavage reagents. A map should contain enough peptides to be meaningful. On the other hand, if there are too many fragments, the map might lose its specificity because many proteins will then have the same profiles.

#### Isolation and Purification

Isolation and purification are necessary for analysis of bulk drugs or dosage forms containing interfering excipients and carrier proteins and, when required, will be specified in the monograph. Quantitative recovery of protein from the dosage form should be validated.

#### Selective Cleavage of Peptide Bonds

The selection of the approach used for the cleavage of peptide bonds will depend on the protein under test. This selection process involves determination of the type of cleavage to be employed—enzymatic or chemical—and the type of cleavage agent within the chosen category. Several cleavage agents and their specificity are shown in [Table 1](#).

Table 1. Examples of Cleavage Agents

Type	Agent	Specificity
Enzymatic	Trypsin, EC 3.4.21.4	C-terminal side of Arg and Lys
	Chymotrypsin, EC 3.4.21.1	C-terminal side of hydrophobic residues (e.g., Leu, Met, Ala, aromatics)
	Pepsin A (Pepsin), EC 3.4.23.1	Nonspecific digest
	Lysyl endopeptidase (Lys-C endopeptidase), EC 3.4.21.50	C-terminal side of Lys
	Glutamyl endopeptidase (Glu-C endopeptidase; V8 protease); (from <i>S. aureus</i> strain V8), EC 3.4.21.19	C-terminal side of Glu and Asp
Chemical	Peptidyl-Asp metalloendopeptidase (Asp-N endopeptidase), EC 3.4.24.33	N-terminal side of Asp
	Clostrypain (Arg-C endopeptidase), EC 3.4.22.8	C-terminal side of Arg
	Cyanogen bromide	C-terminal side of Met
	2-Nitro-5-thiocyanobenzoic acid	N-terminal side of Cys
	O-Iodosobenzoic acid	C-terminal side of Trp and Tyr
	Dilute acid	Asp and Pro
	BNPS-skatole	Trp

This list is not all-inclusive and will be expanded as other cleavage agents are identified.

Pretreatment of Sample— Depending on the size or the configuration of the protein, different approaches in the pretreatment of samples can be used. For monoclonal antibodies, the heavy and light chains will need to be separated before mapping. If trypsin is used as a cleavage agent for proteins with a molecular mass greater than 100,000 Da, lysine residues must be protected by citraconylation or maleylation; otherwise, too many peptides will be generated.

Pretreatment of the Cleavage Agent— Pretreatment of cleavage agents, especially enzymatic agents, might be necessary for purification purposes to ensure reproducibility of the map. For example, trypsin used as a cleavage agent will have to be treated with tosyl-l-phenylalanine chloromethyl ketone to inactivate chymotrypsin. Other methods, such as purification of trypsin by HPLC or immobilization of enzyme on a gel support, have been successfully used when only a small amount of protein is available.

Pretreatment of the Protein— It might be necessary under certain conditions to concentrate the sample, or to separate the protein from added substances and stabilizers used in the formulation of the product if these interfere with the mapping procedure. Physical procedures used for pretreatment can include ultrafiltration, column chromatography, and lyophilization.

Other pretreatments such as the addition of chaotropic agents (e.g., urea) can be used to unfold the protein prior to mapping. It is often necessary to reduce and alkylate the disulfide bonds prior to digestion in order to allow the enzyme to have full access to cleavage sites and permit some unfolding of the protein.

Digestion with trypsin can introduce ambiguities in the tryptic map as a result of side reactions occurring during the digestion reaction, such as nonspecific cleavage, deamidation, disulfide isomerization, oxidation of methionine residues, or formation of pyroglutamyl groups created from the deamidation of glutamine at the N-terminal side of a peptide.

Furthermore, peaks may be produced by autohydrolysis of trypsin. Their intensities depend on the ratio of trypsin to protein. To avoid autohydrolysis, solutions of proteases may be prepared at a pH that is not optimal (e.g., at pH 5 for trypsin), which would mean that the enzyme would not become active until diluted with the digest buffer.

Establishment of Optimal Digestion Conditions— Factors that affect the completeness and effectiveness of digestion of proteins are those that could affect any chemical or enzymatic reactions.

pH— The digestion mixture pH is empirically determined to ensure the optimal performance of the given cleavage agent. For example, a highly acidic environment (e.g., pH 2, formic acid) is necessary when using cyanogen bromide as a cleavage agent; however, a slightly alkaline environment (pH 8) is optimal when using trypsin as a cleavage agent. As a general rule, the pH of the reaction milieu should not alter the chemical integrity of the protein during the digestion and should not change during the course of the fragmentation reaction.

Temperature— A temperature between 25° and 37° is adequate for most digestions. The temperature used is intended to minimize chemical side reactions. The type of protein under test will dictate the temperature of the reaction milieu because some proteins are more susceptible to denaturation as the temperature of the reaction increases. For example, digestion of recombinant bovine somatotropin is conducted at 4° because at higher temperatures it will precipitate during digestion.

Time— If a sufficient amount of sample is available, a time course study is considered in order to determine the optimum time to obtain a reproducible map and avoid incomplete digestion. Time of digestion varies from 2 to 30 hours. The reaction is stopped by the addition of an acid that does not interfere with the tryptic map, or by freezing.

Amount of Cleavage Agent— Although excessive amounts of cleavage agent are used to accomplish a reasonably rapid digestion time (i.e., 6 to 20 hours), the amount of cleavage agent is minimized to avoid its contribution to the chromatographic map pattern. A protein-to-protease ratio between 20:1 and 200:1 is generally used. It is recommended that the cleavage agent be added in two or more stages to optimize cleavage. Nonetheless, the final reaction volume remains small enough to facilitate the next step in peptide mapping—the separation step. To sort out digestion artifacts that might be interfering with the subsequent analysis, a blank determination is performed using a digestion control with all the reagents except the test protein.

#### Chromatographic Separation

Many techniques are used to separate peptides for mapping. The selection of a technique depends on the protein being mapped. Techniques that have been successfully used for the separation of peptides are shown in [Table 2](#).

Table 2. Techniques Used for the Separation of Peptides

Reverse-Phase High-Performance Liquid Chromatography (RP-HPLC)
Ion-Exchange Chromatography (IEC)
Hydrophobic Interaction Chromatography (HIC)
Polyacrylamide Gel Electrophoresis (PAGE), nondenaturating
Sodium Dodecyl Sulfate Polyacrylamide Gel Electrophoresis (SDS-PAGE)
Capillary Electrophoresis (CE)
Paper Chromatography
High-Voltage Paper Electrophoresis (HVPE)

In this section, a most widely used reverse-phase HPLC (RP-HPLC) method is described as one of the procedures of chromatographic separation.

The purity of solvents and mobile phases is a critical factor in HPLC separation. HPLC-grade solvents and water that are commercially available are recommended for RP-HPLC. Dissolved gases present a problem in gradient systems where the solubility of the gas in a solvent may be less in a mixture than in a single solvent. Vacuum degassing and agitation by sonication are often used as useful degassing procedures. The solid particles in the solvents are drawn into the HPLC system; they can damage the sealing of pump valves or clog the top of the chromatographic column. Both pre- and post-pump filtration are also recommended.

Chromatographic Column— The selection of a chromatographic column is empirically determined for each protein. Columns with 100 Å or 300 Å pore size and silica support can give optimal separation. For smaller peptides, column packings of octylsilane chemically bonded to totally porous silica articles 3 to 10 µm in diameter (L7) and of octadecylsilane chemically bonded to porous silica or ceramic microparticles 3 to 10 µm in diameter (L1) are more efficient than the butyl silane chemically bonded to totally porous silica particles 5 to 10 µm in diameter (L26).

Solvent— The most commonly used solvent is water with acetonitrile as the organic modifier to which less than 0.1% of trifluoroacetic acid is added. If necessary, add isopropyl alcohol or n-propyl alcohol to solubilize the digest components, provided that the addition does not unduly increase the viscosity of the components.

Mobile Phase— Buffered mobile phases containing phosphate are used to provide some flexibility in the selection of pH conditions, since shifts of pH in the 3.0 to 5.0 range enhance the separation of peptides containing acidic residues (e.g., glutamic and aspartic acids). Sodium or potassium phosphates, ammonium acetate, and phosphoric acid, with a pH between 2 and 7 (or higher for polymer-based supports), have also been used with acetonitrile gradients. Acetonitrile-containing trifluoroacetic acid is also used quite often.

Gradient Selection— Gradients can be linear, nonlinear, or include step functions. A shallow gradient is recommended in order to separate complex mixtures. Gradients are optimized to provide clear resolution of one or two peaks that will become "marker" peaks for the test.

Isocratic Selection— Isocratic HPLC systems using a single mobile phase are used on the basis of their convenience of use and improved detector responses. Optimal composition of a mobile phase to obtain clear resolution of each peak is sometimes difficult to establish. Mobile phases for which slight changes in component ratios or in pH significantly affect retention times of peaks in peptide maps should not be used in isocratic HPLC systems.

Other Parameters— Temperature control of the column is usually necessary to achieve good reproducibility. The flow rates for the mobile phases range from 0.1 to 2.0 mL per minute, and the detection of peptides is performed with a UV detector at 200 to 230 nm. Other methods of detection have been used (e.g., postcolumn derivatization), but they are not as robust or as versatile as UV detection.

System Suitability— The section System Suitability under [Chromatography](#) provides an experimental means for measuring the overall performance of the test method. The acceptance criteria for system suitability depend on the identification of critical test parameters that affect data interpretation and acceptance. These critical parameters are also criteria

...el monitor peptide digestion and peptide analysis. An indicator that the desired digestion endpoint was achieved is the comparison with a reference standard or reference material, which is treated exactly as the article under test. The use of a USP Reference Standard in parallel with the protein under test is critical in the development and establishment of system suitability limits. In addition, a specimen chromatogram should be included with the USP Reference Standard or reference material for comparison purposes. Other indicators may include visual inspection of protein or peptide solubility, the absence of intact protein, or measurement of responses of a digestion-dependent peptide. The critical system suitability parameters for peptide analysis will depend on the particular mode of peptide separation and detection, and on the data analysis requirements.

When peptide mapping is used as an identification test, the system suitability requirements for the identified peptides cover selectivity and precision. In this case, as well as when identification of variant proteins is done, the identification of the primary structure of the peptide fragments in the peptide map provides both a verification of the known primary structure and the identification of protein variants by comparison with the peptide map of the USP Reference Standard or reference material for the specified protein. The use of a digested USP Reference Standard or reference material for a given protein in the determination of peptide resolution is the method of choice. For an analysis of a variant protein, a characterized mixture of a variant and a reference standard can be used, especially if the variant peptide is located in a less-resolved region of the map. The index of pattern consistency can be simply the number of major peptides detected. Peptide pattern consistency can be best defined by the resolution of peptide peaks. Chromatographic parameters—such as peak-to-peak resolution, maximum peak width, peak tailing factors, and column efficiency—may be used to define peptide resolution. Depending on the protein under test and the method of separation used, single peptide or multiple peptide resolution requirements may be necessary.

The replicate analysis of the digest of the USP Reference Standard or reference material for the protein under test yields measures of precision and quantitative recovery. Recovery of the identified peptides is generally ascertained by the use of internal or external peptide standards. The precision is expressed as the relative standard deviation (RSD). Differences in the recovery and precision of the identified peptides are expected; therefore, the system suitability limits will have to be established for both the recovery and the precision of the identified peptides. These limits are unique for a given protein and will be specified in the individual monograph.

Visual comparison of the relative retention times, the peak responses, the number of peaks, and the overall elution pattern is completed initially. It is then complemented and supported by mathematical analysis of the peak response ratios and by the chromatographic profile of a 1:1 (v/v) mixture of sample and USP Reference Standard or reference material digest. If all peaks in the sample digest and in the USP Reference Standard or reference material digest have the same relative retention times and peak response ratios, then the identity of the sample under test is confirmed.

If peaks that initially eluted with significantly different relative retention times are then observed as single peaks in the 1:1 mixture, the initial difference would be an indication of system variability. However, if separate peaks are observed in the 1:1 mixture, this would be evidence of the nonequivalence of the peptides in each peak. If a peak in the 1:1 mixture is significantly broader than the corresponding peak in the sample and USP Reference Standard or reference material digest, it may indicate the presence of different peptides. The use of computer-aided pattern recognition software for the analysis of peptide mapping data has been proposed and applied, but issues related to the validation of the computer software preclude its use in a compendial test in the near future. Other automated approaches have been used that employ mathematical formulas, models, and pattern recognition. Such approaches, for example, the automated identification of compounds by IR spectroscopy and the application of diode-array UV spectral analysis for identification of peptides, have been proposed. These methods have limitations due to inadequate resolutions, co-elution of fragments, or absolute peak response differences between USP Reference Standard or reference material and sample fragments.

The numerical comparison of the retention times and peak areas or peak heights can be done for a selected group of relevant peaks that have been correctly identified in the peptide maps. Peak areas can be calculated using one peak showing relatively small variation as an internal reference, keeping in mind that peak area integration is sensitive to baseline variation and likely to introduce error in the analysis. Alternatively, the percentage of each peptide peak height relative to the sum of all peak heights can be calculated for the sample under test. The percentage is then compared to that of the corresponding peak of the USP Reference Standard or reference material. The possibility of autohydrolysis of trypsin is monitored by producing a blank peptide map that is the peptide map obtained when a blank solution is treated with trypsin.

The minimum requirement for the qualification of peptide mapping is an approved test procedure that includes system suitability as a test control. In general, for an IND, qualification of peptide mapping for a protein is sufficient. As the regulatory approval process for the protein progresses, additional qualifications of the test can include a partial validation of the analytical procedure to provide assurance that the method will perform as intended in the development of a peptide map for the specified protein.

#### Analysis and Identification of Peptides

This section gives guidance on the use of peptide mapping during development in support of regulatory applications.

The use of a peptide map as a qualitative tool does not require the complete characterization of the individual peptide peaks. However, validation of peptide mapping in support of regulatory applications requires rigorous characterization of each of the individual peaks in the peptide map. Methods to characterize peaks range from N-terminal sequencing of each peak followed by amino acid analysis to the use of mass spectroscopy (MS).

For characterization purposes, when N-terminal sequencing and amino acid analysis are used, the analytical separation is scaled up. Because scale-up might affect the resolution of peptide peaks, it is necessary, using empirical data, to assure that there is no loss of resolution due to scale-up. Eluates corresponding to specific peptide peaks are collected, vacuum-concentrated, and chromatographed again, if necessary. Amino acid analysis of fragments may be limited by the peptide size. If the N-terminus is blocked, it may need to be cleared before sequencing. C-terminal sequencing of proteins or a combination of carboxypeptidase digestion and matrix-assisted laser desorption ionization-time-of-flight (MALDI-TOF) MS can also be used for characterization purposes.

The use of MS for characterization of peptide fragments is by direct infusion of isolated peptides or by the use of on-line LC-MS for structure analysis. In general, it includes electrospray and MALDI-TOF analyzers as well as fast atom bombardment (FAB). Tandem MS has also been used to sequence a modified protein and to determine the type of amino acid modification that has occurred. The comparison of mass spectra of the digests before and after reduction provides a method to assign the disulfide bonds to the various sulphydryl-containing peptides.

If regions of the primary structure are not clearly demonstrated by the peptide map, it might be necessary to develop a secondary peptide map. The goal of a validated method of characterization of a protein through peptide mapping is to reconcile and account for at least 95% of the theoretical composition of the protein structure.

#### THE USE OF PEPTIDE MAPPING FOR GENETIC STABILITY EVALUATION

A validated peptide map can be used to assess the integrity of the predicted primary sequence of a protein product (i.e., its genetic stability). It can also be used to determine lot-to-lot consistency of the biotechnology-derived product process. Furthermore, the performance of the protein expression of the production system is best assessed by peptide mapping of the expressed protein. Peptide maps of protein produced at various times of the protein expression process, including a point well beyond the normal protein expression time, compared with those of a USP Reference Standard or reference material, will evaluate the genetic stability of the expression system as a function of time.

Variant protein sequences can arise from a genetic variation at the DNA level (point mutation) or as an error in the translation process. A validated peptide map is the best approach to the detection of protein variants. However, the limitations of the peptide mapping itself must be taken into consideration. The detection of a structured variant is possible only if the corresponding peptide variant is easily isolated and characterized. To establish genetic stability will require the use of a battery of biochemical methods, provided that the variants have properties different from those of the "normal" protein.

#### VALIDATION

##### Critical Factors

Validation of peptide mapping requires that a protocol be designed, outlining in detail the experiment to be conducted and the criteria for acceptance of the map. Criteria for acceptance of mapping include detection limit, specificity, linearity, range, accuracy, precision, and reagent stability. Reproducibility of the peptide map is a critical element in the utilization of such a map as an identity test and for confirming genetic stability. Those technical aspects of peptide mapping that influence the reproducibility of the map will be discussed.

The setting of limits, with respect to quantification (peak area or height) and identification (retention times) for the selected group of relevant peaks is based on empirical observations. These limits detect significant differences between the sample and USP Reference Standard or reference material within a series of analyses.

Another critical issue is the recovery of peptides and its impact on peak area determination and reproducibility and on the establishment of acceptance criteria. The recovery criteria address all aspects of test methodology, from digestion to chromatographic conditions. Determination of peptide recovery includes quantitative amino acid analysis, spike addition, radiolabeling, and UV summation. An overall recovery of about 80% is considered satisfactory. Recovery of individual peptides is more problematic and is handled on a case-by-case basis. The critical factors considered in the validation of a peptide map are as follows.

**Written Test Procedures**— These procedures include a detailed description of the analytical method in which reagents, equipment, sample preparation, method of analysis, and analysis of the data are defined.

**Validation Protocol**— A protocol is prepared that contains a procedure for test validation.

**Acceptance Criteria**— The criteria can be minimal at the early stages, but need to be better defined as validation studies progress.

**Reporting of Results**— Results from the validation study are documented with respect to the analytical parameters listed in the validation protocol.

**Revalidation of the Test Procedure**— If the method used requires alteration that could affect the analytical parameter previously assessed in the validation of the procedure, the test procedure must be revalidated. Significant changes in the processing of the article, in laboratories performing the analysis, in formulation of the bulk or the finished products, and in any other significant parameter will require revalidation of the methods.

#### Requirements

#### Precision—

**Intratest Precision**— This is a measure of the reproducibility of peptide mapping. The two critical steps in peptide mapping are fragmentation (i.e., digestion) and separation of peptides. An acceptable precision occurs where the absolute retention times and the relative peak areas are constant from run to run, and the average variation in retention time is small relative to that of a selected internal reference peak. The reproducibility of the map can be enhanced if a temperature-controlled column oven is used, if an extensive equilibration of the system is performed prior to the start of the test, if a blank (control digest mixture without protein) is run first to minimize “first run effects,” and if a USP Reference Standard or a reference material digest is interspersed periodically with test samples to evaluate chromatographic drift.

The criteria for validation of the fragmentation step are similar to those described below for separation of peptides, but they are met for consecutive tests of a series of separately prepared digests of the protein under test.

The criteria for validation of the separation of peptides step include the following:

1. The average standard deviation of the absolute retention times of all major peaks for a set of consecutive tests of the same digest does not exceed a specified acceptance criterion.
2. The average standard deviation of absolute peak area for all fully resolved major peaks does not exceed a specified percentage.

**Intertest Precision**— This is a measure of the reproducibility of the peptide mapping when the test is performed on different days, by different analysts, in different laboratories, with reagents or enzymes from different suppliers or different lots from the same supplier, with different instruments, on columns of different makes or columns of the same make from different lots, and on individual columns of the same make from the same lot. Although it would be desirable, from a scientific perspective, to validate all of these variables in terms of their impacts on precision, a practical approach is to validate the test using those variables most likely to be encountered under operational conditions. Additional variables can be included when needed.

The experimental design allows the analyst to make comparisons using peak retention times and areas that are expressed relative to a highly reproducible internal reference peak within the same chromatogram. The relative peak area is expressed as the ratio of the peak area to that of the internal reference peak. The relative retention time can be expressed as the difference between the absolute retention time and that of the reference peak. The use of relative values eliminates the need to make separate corrections for differences due to injector-to-injector volumes, units of measure for peak areas, column dimensions, and instrument dead volumes. The variability in the retention times and peak areas for the Intertest Precision experiments is expected to be slightly higher than the variability observed for Intratest Precision.

**Robustness**— Factors such as composition of the Mobile Phase, protease quality or chemical reagent purity, column variation and age, and digest stability are likely to affect the overall performance of the test and its reproducibility. Tolerances for each of the key parameters are evaluated and baseline limits established in case the test is used for routine lot release purposes.

**Mobile Phase**— The composition of the Mobile Phase is optimized to obtain the maximum resolution of peptides throughout the elution profile. A balance between optimal resolution and overall reproducibility is desired. A lower pH might improve peak separation but might shorten the life of the column, resulting in lack of reproducibility. Peptide maps at a pH above and below the pH of the procedure are compared to the peptide map obtained at the pH of the procedure and checked for significant differences; they are also reviewed with respect to the acceptance criteria established in the validation protocol.

**Protease Quality or Chemical Reagent Purity**— A sample of the USP Reference Standard or reference material for the protein under test is prepared and digested with different lots of cleavage agent. The chromatograms for each digest are compared in terms of peak areas, shape, and number. The same procedure can be applied to other critical chemicals or pretreatment procedures used during sample preparation, such as reducing and carboxymethylation reagents.

**Column Considerations**— Column-to-column variability, even within a single lot, can affect the performance of the column in the development of peptide maps. Column size may also lead to significant differences. A USP Reference Standard or reference material of the protein under test is digested and the digest is chromatographed on different lots of column from a single manufacturer. The maps are then evaluated in terms of the overall elution profile, retention times, selectivity resolution, and recovery. To evaluate the overall lifetime of the column in terms of robustness, perform a peptide mapping test on different columns and vary significantly the number of injections (e.g., from 10 injections to 250 injections). The resulting maps can then be compared for significant differences in peak broadening, peak area, and overall resolution. As a column ages, an increase in back pressure might be observed that might affect the peptide maps.

A sensible precaution in the use of peptide mapping columns is to select alternative columns in case the original columns become unavailable or are discontinued. Perform a peptide mapping test using equivalent columns from different manufacturers, and examine the maps. Differences in particle shape and size, pore size and volume, carbon load, and end-capping can lead to significant differences in retention times, elution profile selectivity, resolution, and recovery. Slight modifications in the gradient profile may be required to achieve equivalency of mapping when using columns from different manufacturers. [note—The equivalency between instrumentation used for the validation of the test and for routine quality control testing should be considered. It might be preferable to use the same HPLC system for all applications. Otherwise, equivalency of the systems is determined, which may require some changes in the chromatographic test conditions.]

**Digest Stability**— The length of time a digest can be kept before it is chromatographed, as well as the conditions under which the digest is stored before chromatography, is assessed. Several aliquots from a single digest are stored at different storage conditions and chromatographed. These maps are then evaluated for significant differences.

**Reproducibility**— Determination of various parameters indicated above is repeated using the same USP Reference Standard or reference material and test sample in at least two different laboratories by two analysts equipped with similar HPLC systems. The generated peptide maps are evaluated for significant differences.

**Auxiliary Information**— Please [check for your question in the FAQs](#) before contacting USP.

## 1056 BIOTECHNOLOGY-DERIVED ARTICLES—POLYACRYLAMIDE GEL ELECTROPHORESIS

This chapter provides guidance and procedures used for characterization of biotechnology-derived articles by polyacrylamide gel electrophoresis. This chapter is harmonized with the corresponding chapter in JP and EP. Other characterization tests, also harmonized, are shown in [Biotechnology-Derived Articles—Amino Acid Analysis](#) 1052, [Biotechnology-Derived Articles—Capillary Electrophoresis](#) 1053, [Biotechnology-Derived Articles—Isoelectric Focusing](#) 1054, [Biotechnology-Derived Articles—Peptide Mapping](#) 1055, and [Biotechnology-Derived Articles—Total Protein Assay](#) 1057.

### INTRODUCTION

Polyacrylamide gel electrophoresis (PAGE) is used for the qualitative characterization of proteins in biological preparations, for control of purity, and for quantitative determinations.

This procedure is limited to the analysis of proteins with a weight range of 14,000 to 100,000 Da. It is possible to extend the weight range of an electrophoresis gel by various techniques (e.g., gradient gels or particular buffer systems), but such techniques are not discussed in this chapter. Analytical gel electrophoresis is an appropriate method with which to identify and to assess the homogeneity of proteins in drug substances. These methods are routinely used for the estimation of protein subunit molecular weights and for the determination of the subunit compositions of purified proteins.

Ready-to-use gels and reagents are commercially available and can be used instead of those described in this chapter, provided that they give equivalent results and that they meet the validation requirements.

### GENERAL PRINCIPLE OF ELECTROPHORESIS

Under the influence of an electrical field, charged particles migrate in the direction of the electrode bearing the opposite polarity. In gel electrophoresis, the movements of the particles are retarded by interactions with the surrounding gel matrix, which acts as a molecular sieve. The opposing interactions of the electrical force and molecular sieving result in differential migration rates according to the sizes, shapes, and charges of particles. Because of their different physicochemical properties, different macromolecules of a mixture migrate at different speeds during electrophoresis and thus are separated into discrete fractions. Electrophoretic separations can be conducted in systems without support phases (e.g., free solution separation in capillary electrophoresis) and in stabilizing media, such as thin-layer plates, films, or gels.

### CHARACTERISTICS OF POLYACRYLAMIDE GELS FOR PROTEIN ELECTROPHORESIS

The sieving properties of polyacrylamide gels are established by the three-dimensional network of fibers and pores that is formed as the bifunctional bisacrylamide cross-links adjacent to polyacrylamide chains. Polymerization is catalyzed by a free-radical-generating system composed of ammonium persulfate and N,N,N',N'-tetramethylethylenediamine (TEMED).

As the acrylamide concentration of a gel increases, its effective pore size decreases. The effective pore size of a gel is operationally defined by its sieving properties, that is, by the resistance it imparts to the migration of macromolecules. There are limits to the acrylamide concentrations that can be used. At high acrylamide concentrations, gels break much more easily and are difficult to handle. As the pore size of a gel decreases, the migration rate of a protein through the gel decreases. By adjusting the pore size of a gel, through manipulating the acrylamide concentration, the resolution of the method can be optimized for a given protein product. Thus, a given gel is physically characterized by its respective composition of acrylamide and bisacrylamide.

In addition to the composition of the gel, the state of the protein is an important component of electrophoretic mobility. In the case of proteins, electrophoretic mobility is dependent on the pK value of the charged groups and the size of the molecule. It is influenced by the type, the concentration, and the pH of the buffer; by the temperature and the field strength; and by the nature of the support material.

#### Denaturation with Sodium Dodecyl Sulfate

Denaturing PAGE using sodium dodecyl sulfate (SDS) is the most common mode of electrophoresis used in assessing the pharmaceutical quality of protein products. Typically, analytical electrophoresis of proteins is carried out under conditions that ensure dissociation of the proteins into their individual polypeptide subunits and that minimize aggregation of these subunits. The strongly anionic detergent SDS is used in combination with heat to dissociate the proteins before they are loaded on the gel. The denatured polypeptides bind SDS, become negatively charged, and exhibit a consistent charge-to-weight ratio regardless of protein type. Because the amount of SDS bound is almost always proportional to the molecular weight of the polypeptide and is typically independent of its sequence, SDS-polypeptide complexes migrate through polyacrylamide gels in reasonable accordance with the size of the polypeptide.

The electrophoretic mobilities of the resultant detergent-polypeptide complexes all assume the same functional relationship to the molecular weights of the polypeptides. Migration of SDS derivatives is toward the anode in a predictable manner, with low molecular weight complexes migrating faster than larger ones. This means that the molecular weight of a protein can be estimated from its relative mobility in calibrated SDS PAGE and that a single band in such a gel is a criterion of purity.

Modifications to the polypeptide backbone, such as N- or O-linked glycosylation, however, have a significant impact on the apparent molecular weight of a protein. This is due to the fact that SDS does not bind to a carbohydrate moiety in a manner similar to that of the polypeptide. Thus, a consistent charge-to-weight ratio is not maintained. The apparent molecular weight of proteins having undergone post-translational modifications is not a true reflection of the weight of the polypeptide chain.

#### Reducing Conditions

Polypeptide subunits and their three-dimensional structure can be maintained in proteins by the presence of disulfide bonds. A goal of SDS PAGE analysis under reducing conditions is to disrupt this structure by reducing disulfide bonds. Complete denaturation and dissociation of proteins by treatment with 2-mercaptoethanol or dithiothreitol (DTT) will result in the unfolding of the polypeptide backbone and subsequent complexation with SDS. Under these conditions, the molecular weight of the polypeptide subunits can be calculated by linear regression in the presence of suitable molecular weight standards.

#### Nonreducing Conditions

For some analyses, complete dissociation of protein to peptide subunits is not desirable. In the absence of treatment with reducing agents, disulfide covalent bonds remain intact, preserving the oligomeric form of the protein. Oligomeric SDS-protein complexes migrate more slowly than their SDS-polypeptide subunits. In addition, nonreduced proteins may not be completely saturated with SDS and hence may not bind the detergent in a constant weight ratio. This makes molecular weight determinations of these molecules less straightforward than analyses of fully denatured polypeptides, because, for valid comparisons, it is necessary that both standards and unknown proteins be in similar configurations. However, the staining of a single band in such a gel is a criterion of purity.

#### Characteristics of a Discontinuous Buffer System

The most popular electrophoretic method for the characterization of a complex mixture of proteins involves the use of a discontinuous buffer system consisting of two contiguous, but distinct, gels: a resolving or separating (lower) gel and a stacking (upper) gel. The two gels are cast with different porosities, pHs, and ionic strengths. In addition, different mobile ions are used in the gel and electrode buffers. The buffer discontinuity concentrates large volumes of sample in the stacking gel, resulting in improved resolution. When power is applied, a voltage drop develops across the sample solution that drives the proteins into the stacking gel. Glycinate ions from the electrode buffer follow the proteins into the stacking gel. A moving boundary region is rapidly formed with the highly mobile chloride ions in the front and the relatively slow glycinate ions in the rear. A localized high-voltage gradient forms between the leading and trailing ion fronts, causing the SDS-protein complexes to form into a thin zone (stack) and migrate between the chloride and glycinate phases. Within a broad limit, regardless of the height of the applied sample, all SDS proteins condense into a very narrow region and enter the resolving gel as a well-defined, thin zone of high protein density. The large-pore stacking gel does not retard the migration of most proteins and serves mainly as an anticonvective medium. At the interface between the stacking and resolving gels, the proteins experience a sharp retardation due to the restrictive pore size of the resolving gel. Once in the resolving gel, proteins continue to be slowed by the sieving of the matrix. The glycinate ions overtake the proteins, which then move in a space of uniform pH formed by tris(hydroxymethyl)aminomethane (Tris) and glycine. Molecular sieving causes the SDS-polypeptide complexes to separate on the basis of their molecular weights.

## Preparation of Gels

In a discontinuous buffer SDS-polyacrylamide gel, it is important to pour the resolving gel, let the gel set, and then pour the stacking gel, because the composition of acrylamide–bisacrylamide, buffer, and pH are different.

## Gel Stock Solutions—

30% Acrylamide–Bisacrylamide Solution— Prepare a solution containing 290 g of acrylamide and 10 g of methylene bisacrylamide per L of warm water, and filter. [note—Acrylamide and methylene bisacrylamide are slowly converted during storage to acrylic acid and bisacrylic acid, respectively. This deamidation reaction is catalyzed by light and alkali. The pH of the solution must be 7.0 or lower. Store the solution in dark bottles at room temperature. Fresh solutions are prepared every month.]

Ammonium Persulfate Solution— Prepare a small quantity of solution having a concentration of 100 g of ammonium persulfate per L, and store at 4°. [note—Ammonium persulfate provides the free radicals that drive polymerization of acrylamide and bisacrylamide. Ammonium persulfate decomposes slowly; therefore, prepare fresh solutions weekly.]

TEMED— Use an electrophoresis-grade reagent. [note—TEMED accelerates the polymerization of acrylamide and bisacrylamide by catalyzing the formation of free radicals from ammonium persulfate. Because TEMED works only as a free base, polymerization is inhibited at low pH.]

SDS Solution— Use an electrophoresis-grade reagent. Prepare a solution having a concentration of about 100 g of SDS per L, and store at room temperature.

1.5 M Buffer Solution— Transfer about 90.8 g of Tris to a 500-mL flask, dissolve in 400 mL of water, adjust with hydrochloric acid to a pH of 8.8, dilute with water to volume, and mix.

1 M Buffer Solution— Transfer about 60.6 g of Tris to a 500-mL flask, add 400 mL of water, adjust with hydrochloric acid to a pH of 6.8, dilute with water to volume, and mix.

Plate Preparation— Clean two glass plates (10 cm × 8 cm), the polytef comb, the two spacers, and the silicone rubber tubing (0.6 mm × 35 cm) with mild detergent, rinse thoroughly with water, and blot dry.

Lubricate the spacers and the tubing with nonsilicone grease. Apply the spacers along each of the two short sides of the glass plate 2 mm away from the edges and 2 mm away from the long side corresponding to the bottom of the gel.

Begin to lay the tubing on the glass plate by using one spacer as a guide. Carefully twist the tubing at the bottom of the spacer, and follow the long side of the glass plate. While holding the tubing with one finger along the long side, twist the tubing again, and lay it on the second short side of the glass plate, using the spacer as a guide.

Place the second glass plate in perfect alignment with the first, and hold the gel mold together by hand pressure. Apply two clamps on each of the two short sides of the mold. Carefully apply four clamps on the longer side of the mold, thus forming the bottom of the mold. Verify that the tubing is running along the edge of the glass plates and has not been extruded while placing the clamps. The mold is now ready for the pouring of the gel.

Resolving Gel— In a conical flask, prepare the appropriate volume of solution, containing the desired concentration of acrylamide, as shown in [Table 1](#). Mix the components in the order shown. Before adding the Ammonium Persulfate Solution and the TEMED, pour the solution into a disposable filtration unit equipped with a nitrocellulose filter having a 0.45-μm porosity, and apply vacuum. Allow the solution to degas by swirling the filtration unit, and disconnect the vacuum when no more bubbles are formed in the solution. Add appropriate amounts of Ammonium Persulfate Solution and TEMED, as shown in [Table 1](#); swirl; and pour immediately into the gap between the two glass plates of the mold. Leave sufficient space for the stacking gel (the length of the teeth of the comb plus 1 cm). Using a pipet, carefully overlay the solution with water-saturated isobutyl alcohol. Leave the gel in a vertical position at room temperature for polymerization.

Table 1. Preparation of Resolving Gel

Solution Component	Component Volume (mL) per Gel Mold Volume Below							
	5 mL	10 mL	15 mL	20 mL	25 mL	30 mL	40 mL	50 mL

After polymerization is complete (about 30 minutes later), pour off the overlay, and wash the top of the gel several times with water to remove the isobutyl alcohol overlay and any unpolymerized acrylamide. Drain as much fluid as possible from the top of the gel, then remove any remaining water with the edge of a paper towel.

Stacking Gel—In a conical flask, prepare the appropriate volume of solution containing the desired concentration of acrylamide, as shown in [Table 2](#).

Table 2. Preparation of Stacking Gel

Solution Component	Component Volume (mL) per Gel Mold Volume Below							
	1 mL	2 mL	3 mL	4 mL	5 mL	6 mL	8 mL	10 mL
Water	0.68	1.4	2.1	2.7	3.4	4.1	5.5	6.8
30% Acrylamide–Bisacrylamide Solution	0.17	0.33	0.5	0.67	0.83	1.0	1.3	1.7
1.0 M Buffer Solution	0.13	0.25	0.38	0.5	0.63	0.75	1.0	1.25
SDS Solution	0.01	0.02	0.03	0.04	0.05	0.06	0.08	0.1
Ammonium Persulfate Solution	0.01	0.02	0.03	0.04	0.05	0.06	0.08	0.1
TEMED	0.001	0.002	0.003	0.004	0.005	0.006	0.008	0.01

Mix the components in the order shown. Before adding the Ammonium Persulfate Solution and the TEMED, pour the solution into a disposable filtration unit equipped with a nitrocellulose filter having a 0.45- $\mu$ m porosity, and apply vacuum. Allow the solution to degas by swirling the filtration unit, and disconnect the vacuum when no more bubbles are formed in the solution. Add appropriate amounts of Ammonium Persulfate Solution and TEMED as shown in [Table 2](#), swirl, and pour immediately into the gap between the two glass plates of the mold directly onto the surface of the polymerized Resolving Gel. Immediately insert a clean polytef comb into the stacking gel solution, being careful to avoid trapping air bubbles. Add more stacking gel solution to fill the spaces of the comb completely. Leave the gel in a vertical position, and allow it to polymerize at room temperature. After polymerization is complete (about 30 minutes later), carefully remove the polytef comb, and proceed as directed below.

#### Electrophoretic Separation

Sample Buffer 1—Dissolve 1.89 g of Tris, 5.0 g of SDS, 50 mg of bromophenol blue, and 25.0 mL of glycerol in 100 mL of water. Adjust with hydrochloric acid to a pH of 6.8, and dilute with water to 125 mL. Before use, dilute with an equal volume of water or sample, and mix.

Sample Buffer 2 (for reducing conditions)—Prepare as directed in Sample Buffer 1 except to add 12.5 mL of 2-mercaptoethanol before adjusting the pH. Alternatively, prepare as directed for Sample Buffer 1 except to start with about 1.93 g of Tris and add a suitable quantity of DTT to obtain a final 100  $\mu$ M DTT concentration.

Running Buffer—Dissolve 151.4 g of Tris, 721.0 g of aminoacetic acid (glycine), and 50.0 g of SDS in water; dilute with water to 5000 mL; and mix to obtain a stock solution. Immediately before use, dilute this stock solution with water to 10 times its volume, mix, and adjust to a pH between 8.1 and 8.8.

Procedure—Rinse the wells immediately with water or with the Running Buffer to remove any unpolymerized acrylamide. (If necessary, straighten the teeth of the Stacking Gel with a blunt hypodermic needle attached to a syringe.) Remove the clamps on one short side, carefully pull out the tubing, and replace the clamps. Proceed similarly on the other short side. Remove the tubing from the bottom part of the gel.

Mount the completed gel in the electrophoresis apparatus. Add the electrophoresis buffers to the top and bottom reservoirs. Remove any bubbles that become trapped at the bottom of the gel between the glass plates. [note—Removal is best done with a bent hypodermic needle attached to a syringe. Never prerun the gel before loading the samples, because that will destroy the discontinuity of the buffer systems. Before loading the sample, carefully rinse the slot with Running Buffer.]

Prepare the test and standard solutions in the recommended Sample Buffer, and treat as directed in the individual monograph. Apply the appropriate volume of each solution to the Stacking Gel wells.

Start the electrophoresis under the conditions recommended by the manufacturer of the equipment. Electrophoresis running time and current or voltage may need to be varied in order to achieve optimum separation. Check that the dye front is moving into the Resolving Gel. When the dye has reached the bottom of the gel, stop the electrophoresis. Remove the gel assembly from the apparatus, and separate the glass plates. Remove the spacers, cut off and discard the Stacking Gel, and immediately proceed with staining.

#### Detection of Proteins in Gels

Coomassie staining is the most common protein staining method, with a detection level on the order of 1 to 10  $\mu$ g of protein per band. Silver staining is the most sensitive method for staining proteins in gels, because a band containing 10 to 100 ng can be detected; but the method is more cumbersome and less rugged. All of the steps in gel staining are performed at room temperature with gentle agitation (e.g., on a rocking platform shaker or equivalent). Gloves must be worn when staining the gels to prevent fingerprint residue staining.

#### Reagents—

Coomassie Staining Solution—Prepare a solution of Coomassie brilliant blue R-250 having a concentration of 1.25 g per L in a mixture of water, methanol, and glacial acetic acid (5:4:1). Filter, and store at room temperature.

Destaining Solution—Prepare a mixture of water, methanol, and glacial acetic acid (5:4:1).

Fixing Solution 1—Prepare a mixture of water, methanol, and trichloroacetic acid (5:4:1).

Fixing Solution 2—Transfer 250 mL of methanol to a 500-mL volumetric flask, add 0.27 mL of formaldehyde, dilute with water to volume, and mix.

Silver Nitrate Reagent—To a mixture of 40 mL of 1 M sodium hydroxide and 3 mL of ammonium hydroxide, add, dropwise and with stirring, 8 mL of a 200 g per L solution of silver nitrate; dilute with water to 200 mL, and mix.

Developing Solution—Transfer 2.5 mL of a citric acid solution (2 in 100) and 0.27 mL of formaldehyde to a 500.0-mL volumetric flask, dilute with water to volume, and mix.

Stopping Solution—Prepare a 10% (v/v) solution of acetic acid.

Coomassie Staining—Immerse the gel in an excess of Coomassie Staining Solution, and incubate for at least 1 hour. Remove the Coomassie Staining Solution. Destain the gel with an excess of Destaining Solution. Change the Destaining Solution several times, until the stained protein bands are clearly distinguishable on a clear background. The more thoroughly the gel is destained, the smaller the amount of protein that can be detected. Destaining can be accelerated by including a few g of anion-exchange resin or a small sponge in the Destaining Solution. [note—The acid–alcohol solutions used in this procedure do not completely fix proteins in the gel. This can lead to losses of some low molecular weight proteins during the staining and destaining of thin gels. Permanent fixation is obtainable by incubating the gel in Fixing Solution 1 for 1 hour before it is immersed in the Coomassie Staining

#### Solution.]

Silver Staining— Immerse the gel in an excess of Fixing Solution 2, and incubate for 1 hour. Remove Fixing Solution 2, add fresh Fixing Solution 2, and incubate for at least 1 hour, or overnight if convenient. Discard Fixing Solution 2, and wash the gel in an excess of water for 1 hour. Soak the gel for 15 minutes in a 1% solution of glutaraldehyde (v/v). Wash the gel twice, for 15 minutes each time, with an excess of water. Soak the gel in fresh Silver Nitrate Reagent for 15 minutes in darkness. Wash the gel three times, for 5 minutes each time, with an excess of water. Immerse the gel for about 1 minute in Developing Solution until satisfactory staining has been obtained. Stop the development by incubation in the Stopping Solution for 15 minutes, then rinse the gel with water, and proceed with drying as indicated below.

#### Drying of Gels

For Coomassie staining, after the destaining step, incubate the gel in a glycerol solution (1 in 10) for at least 2 hours. For silver staining, add to the final rinsing step a 5-minute incubation in a glycerol solution (1 in 50).

Immerse two sheets of porous cellophane in water, and incubate for 5 to 10 minutes. Place one of the sheets on a drying frame. Carefully lift the gel, and place it on the cellophane sheet. Remove any trapped air bubbles, and pour a few mL of water around the edges of the gel. Place the second sheet on top, and remove any trapped air bubbles. Complete the assembly of the drying frame. Place in a drying oven, leave at room temperature until dry, or use a commercial gel dryer.

#### Molecular Weight Determination

Molecular weights of proteins are determined by comparison of their mobilities with those of several marker proteins of known molecular weight. Mixtures of proteins with precisely known molecular weights blended for uniform staining are available for calibrating gels. They are available in various molecular weight ranges. Concentrated stock solutions of proteins of known molecular weight are diluted in a sample buffer and loaded on the same gel as the protein sample to be tested.

Immediately after the gel has been run, the position of the bromophenol blue tracking dye is marked to identify the leading edge of the electrophoretic ion front. This can be done by cutting notches in the edges of the gel or by inserting a needle soaked in India ink into the gel at the dye front. After staining, measure the migration distances of each protein band (markers and unknowns) from the top of the Resolving Gel. Divide the migration distance of each protein by the distance traveled by the tracking dye. The normalized migration distances so obtained are called the relative mobilities of the proteins (relative to the dye front) and conventionally denoted as RF. Construct a (semilogarithmic) plot of the logarithm of the molecular weights (MR) of the protein standards as functions of the RF values. [note—The graphs are slightly sigmoid.] From the graph so obtained, estimate the unknown molecular weights by linear regression analysis or interpolation, as long as unknown samples are positioned along the linear part of the graph.

If the proteins of the molecular weight marker are not distributed along 80% of the length of the gel and over the required separation range (i.e., the range covering the product and its dimer or the products and its related impurities), and the separation obtained for the relevant protein bands does not show a linear relationship between the logarithm of the molecular weight and the RF, the test is not valid.

#### Quantification of Impurities

Where the impurity limit is specified in the individual monograph, a reference solution corresponding to that level of impurity is prepared by diluting the test solution. For example, where the limit is 5.0%, a reference solution is a 1 in 20 dilution of the test solution. No impurity—any band other than the main band—in the electropherogram obtained from the test solution is more intense than the main band obtained with the reference solution.

Under validated conditions and when using the Coomassie staining procedure, impurities may be quantified by normalization to the main band, using an integrating densitometer. In this case, the responses must be validated for linearity.

#### 1057 BIOTECHNOLOGY-DERIVED ARTICLES—TOTAL PROTEIN ASSAY

This chapter provides guidance and procedures used for characterization of biotechnology-derived articles. This chapter is harmonized with the corresponding chapter in JP and EP.

Other characterization tests, also harmonized, are provided in [Biotechnology-Derived Articles—Amino Acid Analysis](#) (1052), [Biotechnology-Derived Articles—Capillary Electrophoresis](#) (1053), [Biotechnology-Derived Articles—Isoelectric Focusing](#) (1054), [Biotechnology-Derived Articles—Peptide Mapping](#) (1055), and [Biotechnology-Derived Articles—Polyacrylamide Gel Electrophoresis](#) (1056).

#### INTRODUCTION

The following procedures are provided as illustrations of the determination of total protein content in pharmacopeial preparations. Other techniques, such as HPLC, are also acceptable if total protein recovery is demonstrated. Many of the total protein assay methods described below can be performed successfully using kits from commercial sources. [note—Where water is required, use distilled water.]

#### Method 1

Protein in solution absorbs UV light at a wavelength of 280 nm due to the presence of aromatic amino acids, mainly tyrosine and tryptophan. This property is the basis of Method 1. Protein determination at 280 nm is mainly a function of the tyrosine and tryptophan content of the protein. If the buffer used to dissolve the protein has a high absorbance relative to that of water, there is an interfering substance in the buffer. This interference can be compensated for when the spectrophotometer is adjusted to zero buffer absorbance. The results may be compromised if the interference results in a large absorbance that challenges the limit of sensitivity of the spectrophotometer. Furthermore, at low concentrations protein can be absorbed onto the cuvette, thereby reducing the content in solution. This can be prevented by preparing samples at higher concentrations or by using a nonionic detergent in the preparation. [note—Keep the Test Solution, the Standard Solution, and the buffer at the same temperature during testing.]

Test Solution— Dissolve a suitable quantity of the protein under test in the appropriate buffer to obtain a solution having a concentration of 0.2 to 2 mg per mL.

Standard Solution— Unless otherwise specified in the individual monograph, prepare a solution of USP Reference Standard or reference material for the protein under test in the same buffer and at the same concentration as the Test Solution.

Procedure— Concomitantly determine the absorbances of the Standard Solution and the Test Solution in quartz cells at a wavelength of 280 nm with a suitable spectrophotometer (see [Spectrophotometry and Light-Scattering](#) (851)), using the buffer as the blank. To obtain accurate results, the response should be linear in the range of protein concentrations to be assayed.

Light-Scattering— The accuracy of the UV spectroscopic determination of protein can be decreased by the scattering of light by the test specimen. If the proteins in solution exist as particles comparable in size to the wavelength of the measuring light (250 to 300 nm), scattering of the light beam results in an apparent increase in absorbance of the test specimen. To calculate the absorbance at 280 nm due to light-scattering, determine the absorbances of the Test Solution at wavelengths of 320, 325, 330, 335, 340, 345, and 350 nm. Using the linear regression method, plot the log of the observed absorbance versus the log of the wavelength, and determine the standard curve best fitting the plotted points. From the graph so obtained, extrapolate the absorbance value due to light-scattering at 280 nm. Subtract the absorbance due to light-scattering from the total absorbance at 280 nm to obtain the absorbance value of the protein in solution. Filtration with a filter having a 0.2-μm porosity or clarification by centrifugation may be performed to reduce the effect of light-scattering, especially if the solution is noticeably turbid.

Calculations— Calculate the concentration, CU, of protein in the test specimen by the formula:

$$CS(AU / AS)$$

in which CS is the concentration of the Standard Solution; and AU and AS are the corrected absorbances of the Test Solution and the Standard Solution, respectively (see [Spectrophotometry and Light-Scattering \(851\)](#)).

#### Method 2

This method, commonly referred to as the Lowry assay, is based on the reduction by protein of the phosphomolybdc–tungstic mixed acid chromogen in the Folin-Ciocalteu's phenol reagent, resulting in an absorbance maximum at 750 nm. The Folin-Ciocalteu's phenol reagent reacts primarily with tyrosine residues in the protein, which can lead to variation in the response of the assay to different proteins. Because the method is sensitive to interfering substances, a procedure for precipitation of the protein from the test specimen may be used.

Where separation of interfering substances from the protein in the test specimen is necessary, proceed as directed below for Interfering Substances prior to preparation of the Test Solution. The effect of interfering substances can be minimized by dilution, provided the concentration of the protein under test remains sufficient for accurate measurement.

**Standard Solutions**— Unless otherwise specified in the individual monograph, dissolve the USP Reference Standard or reference material for the protein under test in the buffer used to prepare the Test Solution. Dilute portions of this solution with the same buffer to obtain not fewer than five Standard Solutions having concentrations between 5 and 100 µg of protein per mL, the concentrations being evenly spaced.

**Test Solution**— Dissolve a suitable quantity of the protein under test in the appropriate buffer to obtain a solution having a concentration within the range of the concentrations of the Standard Solutions. An appropriate buffer will produce a pH in the range of 10.0 to 10.5.

**Blank**— Use the buffer used for the Test Solution and the Standard Solutions.

#### Reagents and Solutions—

**Copper Sulfate Reagent**— Dissolve 100 mg of cupric sulfate and 200 mg of sodium tartrate in water, dilute with water to 50 mL, and mix. Dissolve 10 g of sodium carbonate in water to a final volume of 50 mL, and mix. Slowly pour the sodium carbonate solution into the copper sulfate solution with mixing. Prepare this solution fresh daily.

**SDS Solution**— Dissolve 5 g of sodium dodecyl sulfate in water, and dilute with water to 100 mL.

**Sodium Hydroxide Solution**— Dissolve 3.2 g of sodium hydroxide in water, dilute with water to 100 mL, and mix.

**Alkaline Copper Reagent**— Prepare a mixture of Copper Sulfate Reagent, SDS Solution, and Sodium Hydroxide Solution (1:2:1). This reagent may be stored at room temperature for up to 2 weeks.

**Diluted Folin-Ciocalteu's Phenol Reagent**— Mix 10 mL of Folin-Ciocalteu's phenol TS with 50 mL of water. Store in an amber bottle, at room temperature.

**Procedure**— To 1 mL of each Standard Solution, the Test Solution, and the Blank, add 1 mL of Alkaline Copper Reagent, and mix. Allow to stand at room temperature for 10 minutes. Add 0.5 mL of the Diluted Folin-Ciocalteu's Phenol Reagent to each solution, mix each tube immediately, and allow to stand at room temperature for 30 minutes. Determine the absorbances of the solutions from the Standard Solutions and the Test Solution at the wavelength of maximum absorbance at 750 nm with a suitable spectrophotometer (see [Spectrophotometry and Light-Scattering \(851\)](#)), using the solution from the Blank to set the instrument to zero.

**Calculations**— [note—The relationship of absorbance to protein concentration is nonlinear; however, if the standard curve concentration range is sufficiently small, it will approach linearity.] Using the linear regression method, plot the absorbances of the solutions from the Standard Solutions versus the protein concentrations, and determine the standard curve best fitting the plotted points. From the standard curve so obtained and the absorbance of the Test Solution, determine the concentration of protein in the Test Solution.

#### interfering substances

In the following procedure, deoxycholate–trichloroacetic acid is added to a test specimen to remove interfering substances by precipitation of proteins before testing. This technique also can be used to concentrate proteins from a dilute solution.

**Sodium Deoxycholate Reagent**— Prepare a solution of sodium deoxycholate in water having a concentration of 150 mg in 100 mL.

**Trichloroacetic Acid Reagent**— Prepare a solution of trichloroacetic acid in water having a concentration of 72 g in 100 mL.

**Procedure**— Add 0.1 mL of Sodium Deoxycholate Reagent to 1 mL of a solution of the protein under test. Mix on a vortex mixer, and allow to stand at room temperature for 10 minutes. Add 0.1 mL of Trichloroacetic Acid Reagent, and mix on a vortex mixer. Centrifuge at 3000 × g for 30 minutes, decant the liquid, and remove any residual liquid with a pipet. Redissolve the protein pellet in 1 mL of Alkaline Copper Reagent. Proceed as directed for the Test Solution.

**note**—Color development reaches a maximum in 20 to 30 minutes during incubation at room temperature, after which there is a gradual loss of color. Most interfering substances cause a lower color yield; however, some detergents cause a slight increase in color. A high salt concentration may cause a precipitate to form. Because different protein species may give different color response intensities, the standard protein and test protein should be the same.

#### Method 3

This method, commonly referred to as the Bradford assay, is based on the absorption shift from 470 nm to 595 nm observed when the brilliant blue G dye binds to protein. The brilliant blue G dye binds most readily to arginyl and lysyl residues in the protein, which can lead to variation in the response of the assay to different proteins.

**Standard Solutions**— Unless otherwise specified in the individual monograph, dissolve the USP Reference Standard or reference material for the protein under test in the buffer used to prepare the Test Solution. Dilute portions of this solution with the same buffer to obtain not fewer than five Standard Solutions having concentrations between 100 µg and 1 mg of protein per mL, the concentrations being evenly spaced.

**Test Solution**— Dissolve a suitable quantity of the protein under test in the appropriate buffer to obtain a solution having a concentration within the range of the concentrations of the Standard Solutions.

**Blank**— Use the buffer used to prepare the Test Solution and the Standard Solutions.

**Coomassie Reagent**— Dissolve 100 mg of brilliant blue G<sup>+</sup> in 50 mL of alcohol. [note—Not all dyes have the same brilliant blue G content, and different products may give different results.] Add 100 mL of phosphoric acid, dilute with water to 1 L, and mix. Pass the solution through filter paper (Whatman No. 1 or equivalent), and store the filtered reagent in an amber bottle at room temperature. [note—Slow precipitation of the dye will occur during storage of the reagent. Filter the reagent before use.]

**Procedure**— Add 5 mL of the Coomassie Reagent to 100 µL of each Standard Solution, the Test Solution, and the Blank, and mix by inversion. Avoid foaming, which will lead to poor reproducibility. Determine the absorbances of the solutions from the Standard Solutions and the Test Solution at 595 nm with a suitable spectrophotometer (see [Spectrophotometry and Light-Scattering \(851\)](#)), using the Blank to set the instrument to zero. [note—Do not use quartz (silica) spectrophotometer cells: the dye binds to this material. Because different protein species may give different color response intensities, the standard protein and test protein should be the same.]

There are relatively few interfering substances, but detergents and ampholytes in the test specimen should be avoided. Highly alkaline specimens may interfere with the acidic reagent.

**Calculations**— [note—The relationship of absorbance to protein concentration is nonlinear; however, if the standard curve concentration range is sufficiently small, it will approach linearity.] Using the linear regression method, plot the absorbances of the solutions from the Standard Solutions versus the protein concentrations, and determine the standard curve best fitting the plotted points. From the standard curve so obtained and the absorbance of the Test Solution, determine the concentration of protein in the Test Solution.

#### Method 4

This method, commonly referred to as the bicinchoninic acid or BCA assay, is based on reduction of the cupric (Cu<sup>2+</sup>) ion to cuprous (Cu<sup>1+</sup>) ion by protein. The bicinchoninic acid reagent is used to detect the cuprous ion. The method has few interfering substances. When interfering substances are present, their effect may be minimized by dilution, provided that the concentration of the protein under test remains sufficient for accurate measurement.

Standard Solutions— Unless otherwise specified in the individual monograph, dissolve the USP Reference Standard or reference material for the protein under test in the buffer used to prepare the Test Solution. Dilute portions of this solution with the same buffer to obtain not fewer than five Standard Solutions having concentrations between 10 and 1200 µg of protein per mL, the concentrations being evenly spaced.

Test Solution— Dissolve a suitable quantity of the protein under test in the appropriate buffer to obtain a solution having a concentration within the range of the concentrations of the Standard Solutions.

Blank— Use the buffer used to prepare the Test Solution and the Standard Solutions.

#### Reagents—

BCA Reagent— Dissolve about 10 g of bicinchoninic acid, 20 g of sodium carbonate monohydrate, 1.6 g of sodium tartrate, 4 g of sodium hydroxide, and 9.5 g of sodium bicarbonate in water. Adjust, if necessary, with sodium hydroxide or sodium bicarbonate to a pH of 11.25. Dilute with water to 1 L, and mix.

Copper Sulfate Reagent— Dissolve about 2 g of cupric sulfate in water to a final volume of 50 mL.

Copper-BCA Reagent— Mix 1 mL of Copper Sulfate Reagent and 50 mL of BCA Reagent.

Procedure— Mix 0.1 mL of each Standard Solution, the Test Solution, and the Blank with 2 mL of the Copper-BCA Reagent. Incubate the solutions at 37° for 30 minutes, note the time, and allow to come to room temperature. Within 60 minutes following the incubation time, determine the absorbances of the solutions from the Standard Solutions and the Test Solution in quartz cells at 562 nm with a suitable spectrophotometer (see [Spectrophotometry and Light-Scattering \(851\)](#)), using the Blank to set the instrument to zero. The color intensity continues to increase gradually after the solutions are cooled to room temperature. If substances that will cause interference in the test are present, proceed as directed for Interfering Substances under Method 2. Because different protein species may give different color response intensities, the standard protein and test protein should be the same.

Calculations— [note—The relationship of absorbance to protein concentration is nonlinear; however, if the standard curve concentration range is sufficiently small, it will approach linearity.] Using the linear regression method, plot the absorbances of the solutions from the Standard Solutions versus the protein concentrations, and determine the standard curve best fitting the plotted points. From the standard curve so obtained and the absorbance of the Test Solution, determine the concentration of protein in the Test Solution.

#### Method 5

This method, commonly referred to as the Biuret assay, is based on the interaction of cupric (Cu<sup>2+</sup>) ion with protein in an alkaline solution and the resultant development of absorbance at 545 nm.

Standard Solutions— Unless otherwise specified in the individual monograph, prepare a solution of Albumin Human for which the protein content has been previously determined by nitrogen analysis (using the nitrogen-to-protein conversion factor of 6.25) or of the USP Reference Standard or reference material for the protein under test in sodium chloride solution (9 in 1000). Dilute portions of this solution with sodium chloride solution (9 in 1000) to obtain not fewer than three Standard Solutions having concentrations between 0.5 and 10 mg per mL, the concentrations being evenly spaced. [note—Low responses may be observed if the sample under test has a significantly different level of proline than that of Albumin Human. A different standard protein may be employed in such cases.]

Test Solution— Prepare a solution of the test protein in sodium chloride solution (9 in 1000) having a concentration within the range of the concentrations of the Standard Solutions.

Blank— Use sodium chloride solution (9 in 1000).

Biuret Reagent— Dissolve about 3.46 g of cupric sulfate in 10 mL of hot water, and allow to cool (Solution 1). Dissolve about 34.6 g of sodium citrate dihydrate and 20.0 g of sodium carbonate in 80 mL of hot water, and allow to cool (Solution 2). Mix Solution 1 and Solution 2, and dilute with water to 200 mL. This Biuret Reagent is stable at room temperature for 6 months. Do not use the reagent if it develops turbidity or contains any precipitate.

Procedure— To one volume of a solution of the Test Solution add an equal volume of sodium hydroxide solution (6 in 100), and mix. Immediately add a volume of Biuret Reagent equivalent to 0.4 volume of the Test Solution, and mix. Allow to stand at a temperature between 15° and 25° for not less than 15 minutes. Within 90 minutes after the addition of the Biuret Reagent, determine the absorbances of the Standard Solutions and the solution from the Test Solution at the wavelength of maximum absorbance at 545 nm with a suitable spectrophotometer (see [Spectrophotometry and Light-Scattering \(851\)](#)), using the Blank to set the instrument to zero. [note—Any solution that develops turbidity or a precipitate is not acceptable for calculation of protein concentration.]

Calculations— Using the least-squares linear regression method, plot the absorbances of the Standard Solutions versus the protein concentrations, determine the standard curve best fitting the plotted points, and calculate the correlation coefficient for the line. [note—Within the given range of the standards, the relationship of absorbance to protein concentration is approximately linear.] A suitable system is one that yields a line having a correlation coefficient of not less than 0.99. From the standard curve and the absorbance of the Test Solution, determine the concentration of protein in the test specimen, making any necessary correction.

Interfering Substances— To minimize the effect of interfering substances, the protein can be precipitated from the initial test specimen as follows. Add 0.1 volume of 50% trichloroacetic acid to 1 volume of a solution of the test specimen, withdraw the supernatant layer, and dissolve the precipitate in a small volume of 0.5 N sodium hydroxide. Use the solution so obtained to prepare the Test Solution.

Comments— This test shows minimal difference between equivalent IgG and albumin samples. Addition of the sodium hydroxide and the Biuret Reagent as a combined reagent, insufficient mixing after the addition of the sodium hydroxide, or an extended time between the addition of the sodium hydroxide solution and the addition of the Biuret Reagent will give IgG samples a higher response than albumin samples. The trichloroacetic acid method used to minimize the effects of interfering substances can also be used to determine the protein content in test specimens at concentrations below 500 µg per mL.

#### Method 6

This fluorometric method is based on the derivatization of the protein with o-phthalaldehyde (OPA), which reacts with the primary amines of the protein (i.e., NH<sub>2</sub>-terminal amino acid and the ε-amino group of the lysine residues). The sensitivity of the test can be increased by hydrolyzing the protein before testing. Hydrolysis makes the ε-amino group of the constituent amino acids of the protein available for reaction with the o-phthalaldehyde reagent. The method requires very small quantities of the protein.

Primary amines, such as tris(hydroxymethyl)aminomethane and amino acid buffers, react with o-phthalaldehyde and must be avoided or removed. Ammonia at high concentrations will react with o-phthalaldehyde as well. The fluorescence obtained when amine reacts with o-phthalaldehyde can be unstable. The use of automated procedures to standardize this procedure may improve the accuracy and precision of the test.

Standard Solutions— Unless otherwise specified in the individual monograph, dissolve the USP Reference Standard or reference material for the protein under test in the buffer used to prepare the Test Solution. Dilute portions of this solution with the same buffer to obtain not fewer than five Standard Solutions having concentrations between 10 and 200 µg of protein per mL, the concentrations being evenly spaced.

Test Solution— Dissolve a suitable quantity of the protein under test in the appropriate buffer to obtain a solution having a concentration within the range of the concentrations of the Standard Solutions.

Blank— Use the buffer used to prepare the Test Solution and the Standard Solutions.

#### Reagents—

Borate Buffer— Dissolve about 61.83 g of boric acid in water, and adjust with potassium hydroxide to a pH of 10.4. Dilute with water to 1 L, and mix.

Stock OPA Reagent— Dissolve about 120 mg of o-phthalaldehyde in 1.5 mL of methanol, add 100 mL of Borate Buffer, and mix. Add 0.6 mL of polyoxyethylene (23) lauryl ether, and mix. This solution is stable at room temperature for at least 3 weeks.

OPA Reagent— To 5 mL of Stock OPA Reagent add 15 µL of 2-mercaptoethanol. Prepare at least 30 minutes prior to use. This reagent is stable for one day.

Procedure— Adjust each of the Standard Solutions and the Test Solution to a pH between 8 and 10.5. Mix 10 µL of the Test Solution and each of the Standard Solutions with 100 µL of

A Reagent, and allow to stand at room temperature for 15 minutes. Add 3 mL of 0.5 N sodium hydroxide, and mix. Using a suitable fluorometer (see [Spectrophotometry and Light Scattering](#) 851), determine the fluorescent intensities of solutions from the Standard Solutions and the Test Solution at an excitation wavelength of 340 nm and an emission wavelength between 440 and 455 nm. [note—The fluorescence of an individual specimen is read only once because irradiation decreases the fluorescent intensity.]

**Calculations**— The relationship of fluorescence to protein concentration is linear. Using the linear regression method, plot the fluorescent intensities of the solutions from the Standard Solutions versus the protein concentrations, and determine the standard curve best fitting the plotted points. From the standard curve so obtained and the fluorescent intensity of the Test Solution, determine the concentration of protein in the test specimen.

#### Method 7

This method is based on nitrogen analysis as a means of protein determination. Interference caused by the presence of other nitrogen-containing substances in the test specimen can affect the determination of protein by this method. Nitrogen analysis techniques destroy the protein under test but are not limited to protein presentation in an aqueous environment.

**Procedure 1**— Determine the nitrogen content of the protein under test as directed under [Nitrogen Determination](#) 461. Commercial instrumentation is available for the Kjeldahl nitrogen assay.

**Procedure 2**— Commercial instrumentation is available for nitrogen analysis. Most nitrogen analysis instruments use pyrolysis (i.e., combustion of the sample in oxygen at temperatures approaching 1000°), which produces nitric oxide (NO) and similar oxides of nitrogen (NOx) from the nitrogen present in the test protein. Some instruments convert the nitric oxides to nitrogen gas, which is quantified with a thermal conductivity detector. Other instruments mix nitric oxide (NO) with ozone (O3) to produce excited nitrogen dioxide (NO2), which emits light when it decays and can be quantified with a chemiluminescence detector. A protein reference material or reference standard that is relatively pure and is similar in composition to the test proteins is used to optimize the injection and pyrolysis parameters and to evaluate consistency in the analysis.

**Calculations**— The protein concentration is calculated by dividing the nitrogen content of the sample by the known nitrogen content of the protein. The known nitrogen content of the protein can be determined from the chemical composition of the protein or by comparison with the nitrogen content of the USP Reference Standard or reference material.

\* Dye purity is important in the reagent preparation. Serva Blue G (Crescent Chemical Company, Hauppauge, NY) is an acceptable grade.

Auxiliary Information— Please [check for your question in the FAQs](#) before contacting USP.

## 1058 ANALYTICAL INSTRUMENT QUALIFICATION

### INTRODUCTION

A large variety of laboratory equipment, instruments, and computerized analytical systems, ranging from simple nitrogen evaporators to complex multiple-function technologies (see [Instrument Categories](#)), are used in the pharmaceutical industry to acquire data to help ensure that products are suitable for their intended use. An analyst's objective is to consistently obtain reliable and valid data suitable for the intended purpose. Depending on the applications, users validate their procedures, calibrate their instruments, and perform additional instrument checks, such as system suitability tests and analysis of in-process quality control check samples to help ensure that the acquired data are reliable. With the increasing sophistication and automation of analytical instruments, an increasing demand has been placed on users to qualify their instruments.

Unlike method validation and system suitability activities, analytical instrument qualification (AIQ) currently has no specific guidance or procedures. Competing opinions exist regarding instrument qualification and validation procedures and the roles and responsibilities of those who perform them. Consequently, various approaches have been used for instrument qualification, approaches that require varying amounts of resources and generate widely differing amounts of documentation. This chapter provides a scientific approach to AIQ and considers AIQ as one of the major components required for generating reliable and consistent data. Note that the amount of rigor applied to the qualification process will depend on the complexity and intended use of the instrumentation. This approach emphasizes AIQ's place in the overall process of obtaining reliable data from analytical instruments.

#### Validation versus Qualification

In this chapter, the term validation is used for manufacturing processes, analytical procedures, and software procedures and the term qualification is used for instruments. Thus, the phrase "analytical instrument qualification" (AIQ) is used for the process of ensuring that an instrument is suitable for its intended application.

### COMPONENTS OF DATA QUALITY

There are four critical components involved in the generation of reliable and consistent data (quality data). [Figure 1](#) shows these components as layered activities within a quality triangle. Each layer adds to the overall quality. Analytical instrument qualification forms the base for generating quality data. The other components essential for generating quality data are analytical method validation, system suitability tests, and quality control check samples. These quality components are described below.

Figure 1. Components of data quality.

#### Analytical Instrument Qualification

AIQ is the collection of documented evidence that an instrument performs suitably for its intended purpose. Use of a qualified instrument in analyses contributes to confidence in the validity of generated data.

#### Analytical Method Validation

Analytical method validation is the collection of documented evidence that an analytical procedure is suitable for its intended use. Use of a validated procedure with qualified analytical instruments provides confidence that the procedure will generate test data of acceptable quality. Additional guidance on validation of compendial procedures may be found in the general information chapter [Validation of Compendial Procedures](#) (1225).

#### System Suitability Tests

System suitability tests verify that the system will perform in accordance with the criteria set forth in the procedure. These tests are performed along with the sample analyses to ensure that the system's performance is acceptable at the time of the test. USP general chapter [Chromatography](#) (621) presents a more detailed discussion of system suitability tests as related to chromatographic systems.

#### Quality Control Check Samples

Many analysts carry out their tests on instruments standardized using reference materials and/or calibration standards. Some analyses also require the inclusion of quality control check samples to provide an in-process or ongoing assurance of the test's suitable performance. In this manner, AIQ and analytical method validation contribute to the quality of analysis before analysts conduct the tests. System suitability tests and quality control checks help ensure the quality of analytical results immediately before or during sample analysis.

### ANALYTICAL INSTRUMENT QUALIFICATION PROCESS

The following sections address in detail the AIQ process. The other three components of building quality into analytical data—analytical method validation, system suitability tests, and quality control check samples—are not within the scope of this chapter.

#### Qualification Phases

Instrument qualification is not a single continuous process, but instead results from several discrete activities. For convenience, these activities can be grouped into four phases: design qualification (DQ), installation qualification (IQ), operational qualification (OQ), and performance qualification (PQ).

Some AIQ activities cover more than one qualification phase, and analysts potentially could perform them during more than one of the phases (see [Table 1](#)). However, in many instances there is need for specific order to the AIQ activities; for example, installation qualification must occur first in order to initiate other qualification activities. The AIQ activities will be defined and documented.

Table 1. Timing, Applicability, and Activities for Each Phase of Analytical Instrument Qualification\*

Design Qualification	Installation Qualification	Operational Qualification	Performance Qualification
Timing and Applicability			
Prior to purchase of a new model of instrument	At installation of each instrument (new, old, or existing unqualified)	After installation or major repair of each instrument	Periodically at specified intervals for each instrument
Activities			
Assurance of manufacturer's DQ	Description	↔ Fixed parameters	Preventive maintenance and repairs
Assurance of adequate support availability from manufacturer	Instrument delivery		Establish practices to address operation, calibration, maintenance, and change control
Instrument's fitness for use in laboratory	Utilities/facility	↔ Environment	
	Assembly and installation		
	Network and data storage	↔ Secure data storage, backup, and archive	
	Installation verification	↔ Instrument function tests	↔ Performance checks

\* Activities under each phase are usually performed as given in the table. However, in some cases, it may be more appropriate to perform or combine a given activity with another phase. Such activities spanning more than one qualification phase are shown as connected by double arrows. If an activity listed under a given phase is performed under another phase, it is not necessary to repeat the activity under the phase where the activity is listed. Performing the activity is far more important than the phase under which the activity is performed.

#### Design Qualification

Design qualification (DQ) is the documented collection of activities that define the functional and operational specifications of the instrument and criteria for selection of the vendor, based on the intended purpose of the instrument. Design qualification (DQ) may be performed not only by the instrument developer or manufacturer but also may be performed by the user. The manufacturer is generally responsible for robust design and maintaining information describing how the analytical instrument is manufactured (design specifications, functional requirements, etc.) and tested before shipment to users. Nonetheless, the user should ensure that commercial off-the-shelf (COTS) instruments are suitable for their intended application and that the manufacturer has adopted a quality system that provides for reliable equipment. Users should also determine the manufacturer's capability for support installation, services, and training. This determination might be aided by the user's previous interaction with the manufacturer.

#### Installation Qualification

Installation qualification (IQ) is the documented collection of activities necessary to establish that an instrument is delivered as designed and specified, and is properly installed in the selected environment, and that this environment is suitable for the instrument. IQ applies to an instrument that is new or was pre-owned, or to any instrument that exists on site but has not been previously qualified. Relevant parts of IQ would also apply to a qualified instrument that has been transported to another location or is being reinstalled for other reasons, such as prolonged storage. The activities and documentation typically associated with IQ are as follows.

**Description**— Provide a description of the instrument or the collection of instrument components, including its manufacturer, model, serial number, software version, and location. Use drawings and flow charts where appropriate.

**Instrument Delivery**— Ensure that the instrument, software, manuals, supplies, and any other instrument accessories arrive as specified in the purchase order and that they are undamaged. For a pre-owned or existing instrument, manuals and documentation should be obtained.

**Utilities/Facility/Environment**— Verify that the installation site satisfactorily meets manufacturer-specified environmental requirements.

**Assembly and Installation**— Assemble and install the instrument, and perform any preliminary diagnostics and testing. Assembly and installation may be done by the manufacturer, vendor, specialized engineers, or qualified in-house personnel. Manufacturer-established installation tests and guides provide a valuable baseline reference for determining instrument acceptance. Any abnormal event observed during assembly and installation merits documenting. Installation packages purchased from the manufacturer or the vendor may, however, need to be supplemented with user-specific criteria.

**Network and Data Storage**— Some analytical systems require users to provide network connections and data storage capabilities at the installation site. When required, connect the

instrument to the network, and check its functionality.

Installation Verification— Perform the initial diagnostics and testing of the instrument after installation.

#### Operational Qualification

After a successful IQ, the instrument is ready for OQ testing. Operational qualification (OQ) is the documented collection of activities necessary to demonstrate that an instrument will function according to its operational specification in the selected environment. Testing activities in the OQ phase may consist of these test parameters.

Fixed Parameters— These tests measure the instrument's nonchanging parameters such as length, height, weight, voltage inputs, acceptable pressures, and loads. If the manufacturer-supplied specifications for these parameters satisfy the user, the test requirements may be waived. However, if the user wants to confirm the parameters, testing can be performed at the user's site. Fixed parameters do not change over the life of the instrument, and therefore never need redetermination. [note—These tests could also be performed during the IQ phase (see [Table 1](#)); if so, fixed parameters need not be redetermined as part of OQ testing.]

Secure Data Storage, Backup, and Archiving— When applicable, test secure data handling such as storage, backup, audit trails, and archiving at the user's site according to written procedures.

Instrument Function Tests— Instrument functions required by the user should be tested to verify that the instrument operates as intended by the manufacturer. Manufacturer-supplied information is useful in identifying specifications for these parameters and in designing tests to evaluate the identified parameters. Users, or their qualified designees, should perform these tests to verify that the instrument meets manufacturer or user specifications in the user's environment.

The extent of OQ testing that an instrument undergoes depends on its intended applications. Therefore, no specific OQ tests for any instrument or application are offered in this chapter.

Routine analytical tests do not constitute OQ testing. OQ tests are specifically designed to verify the instrument's operation according to specifications in the user's environment, and repeating the testing at regular intervals may not be required. However, when the instrument undergoes major repairs or modifications, relevant OQ and/or PQ tests should be repeated to verify whether the instrument continues to operate satisfactorily. If an instrument is moved to another location, an assessment should be made of what, if any, OQ test should be repeated.

OQ tests can be modular or holistic. Modular testing of individual components of a system may facilitate interchanging of such components without requalification. Holistic tests, which involve the entire system, are also acceptable.

#### Performance Qualification

Performance qualification (PQ) is the documented collection of activities necessary to demonstrate that an instrument consistently performs according to the specifications defined by the user, and is appropriate for the intended use. After IQ and OQ have been performed, the instrument's continued suitability for its intended use is demonstrated through performance qualification. The PQ phase may include the following parameters.

Performance Checks— Set up a test or series of tests to verify the acceptable performance of the instrument for its intended use. PQ tests are usually based on the instrument's typical on-site applications and may consist of analyzing known components or standards. The tests should be based on good science and reflect the general intended use of the instrument. Some system suitability tests or quality control checks that are performed concurrently with the test samples can be used to demonstrate that the instrument is performing suitably. PQ tests may resemble those performed during OQ, but the specifications for their results may be set differently if required. Nevertheless, user specifications for PQ tests should demonstrate trouble-free instrument operation for the intended applications. As is the case with OQ testing, PQ tests may be modular or holistic.

Testing frequency depends on the ruggedness of the instrument and the criticality of the tests performed. Testing may be unscheduled—for example, each time the instrument is used. It may also be scheduled for regular intervals. Experience with the instrument can influence this decision. It may be useful to repeat the same PQ tests each time the instrument is used so that a history of the instrument's performance can be compiled. Alternatively, the instrument may be incorporated into an integrated support system to assure that it remains continually qualified. Some system suitability tests or quality control checks that are performed concurrently with the test samples also imply that the instrument is performing suitably.

Preventive Maintenance and Repairs— When an instrument fails to meet PQ test specifications, it requires maintenance or repair. A periodic preventive maintenance may also be recommended for many instruments. The relevant PQ test(s) should be repeated after the needed maintenance or repair to ensure that the instrument remains qualified.

Practices for Operation, Calibration, Maintenance, and Change Control— Establish practices to maintain and calibrate the instrument. Each maintenance and calibration activity should be documented.

#### ROLES AND RESPONSIBILITIES

##### Users

Users are ultimately responsible for instrument operations and data quality. The user's group encompasses analysts, their supervisors, instrument specialists, and organization management. Users should be adequately trained in the instrument's use, and their training records should be maintained as required by the regulations.

Users should also be responsible for qualifying their instruments because their training and expertise in the use of instruments make them the best-qualified group to design the instrument test(s) and specification(s) necessary for successful AIQ. Consultants, equipment manufacturer or vendors, validation specialists, and quality assurance (QA) personnel can advise and assist as needed, but the final responsibility for qualifying instruments lies with the users. The users must also maintain the instrument in a qualified state by routinely performing PQ.

##### Quality Unit

The role of the Quality Unit in AIQ remains the same as for any other regulated activity. Quality personnel are responsible for assuring that the AIQ process meets compliance requirements, that processes are being followed, and that the intended use of the equipment is supported by valid and documented data.

##### Manufacturers

Manufacturers and developers are responsible for DQ when designing the instrument. They are also responsible for validation of relevant processes used in manufacturing and assembly of the instrument. Manufacturers should test the assembled instruments before shipping them to users.

Finally, it is desirable that manufacturers and vendors should notify all known users about hardware defects discovered after a product's release; offer user training, service, repair, and installation support; and invite user audits as necessary.

#### SOFTWARE VALIDATION

Software used for analytical work can be classified into three categories: firmware; instrument control, data acquisition, and processing software; and stand-alone software. Although software validation is not the primary focus of this chapter, the following sections describe in which cases this activity is under the scope of the analytical instrument qualification.

##### Firmware

Computerized analytical instruments contain integrated chips with low-level software (firmware). Such instruments will not function without properly operating firmware, and users generally cannot alter firmware design or function. Firmware is therefore considered a component of the instrument itself. Indeed, the qualification of hardware is not possible without operating it via its firmware. Thus, when the hardware (that is, the analytical instrument) is qualified at the user's site, the integrated firmware is also essentially qualified. No separate on-site qualification of the firmware is needed. Whenever possible, the firmware version should be recorded as part of the IQ activities. Any changes made to firmware versions should be tracked through change control of the instrument (see Change Control, below).

##### Instrument Control, Data Acquisition, and Processing Software

Software for instrument control, data acquisition, and processing for many of today's computerized instruments is loaded on a computer connected to the instrument. Operation of the instrument is then controlled via the software, leaving fewer operating controls on the instrument. Also, the software is needed for data acquisition and postacquisition calculations.

Thus, both hardware and software, their functions inextricably intertwined, are critical to providing analytical results.

The manufacturer should perform DQ, validate this software, and provide users with a summary of validation. At the user site, holistic qualification, which involves the entire instrument and software system, is more efficient than modular validation of the software alone. Thus, the user qualifies the instrument control, data acquisition, and processing software by qualifying the instrument according to the AIQ process.

#### Stand-Alone Software

An authoritative guide for validating stand-alone software, such as LIMS, is available.<sup>1</sup> The validation process is administered by the software developer, who also specifies the development model appropriate for the software. Validation takes place in a series of activities planned and executed through various stages of the development cycle.

#### CHANGE CONTROL

Changes to instruments, including software, become inevitable as manufacturers add new features and correct known defects. However, implementing all such changes may not always benefit users. Users should therefore adopt changes they deem useful or necessary and should also assess the effects of changes to determine what, if any, requalification is required. The change control process enables them to do this.

Change control may follow the DQ/IQ/OQ/PQ classification process. For DQ, evaluate the changed parameters, and determine whether need for the change warrants implementing it. If implementation of the change is needed, install the changes to the system during IQ. Evaluate which of the existing OQ and PQ tests need revision, deletion, or addition as a result of the installed change. Where the change calls for additions, deletions, or revisions to the OQ or PQ tests, follow the procedure outlined below.

**Operational Qualification—** Revise OQ tests as necessitated by the change. Perform the relevant tests affected by the change. This ensures the instrument's effective operation after the change is installed.

**Performance Qualification—** Revise PQ tests as necessitated by the change. Perform the PQ testing after installation of the change if similar testing is not already performed during OQ. In the future, perform the revised PQ testing.

For changes to firmware and to software for instrument control, data acquisition, and processing, change control is performed through DQ/IQ/OQ/PQ of the affected instrument. Change control for stand-alone software requires user-site testing of changed functionality.

#### AIQ DOCUMENTATION

Documents obtained during instrument qualification should be retained in an accessible manner. Where multiple instruments of one kind exist, documents common to all instruments and documents specific to an instrument may be stored separately. During change control, additional documents may supplement those obtained during the qualification process, and both sets of documents should be retained and maintained in a suitable manner that allows for appropriate protection and access.

#### INSTRUMENT CATEGORIES

Modern laboratories typically include a suite of instruments and equipment varying from simple nitrogen evaporators to complex automated instruments. Therefore, applying a single set of principles to qualifying such dissimilar instruments would be scientifically inappropriate. Users are most capable of establishing the level of qualification needed for an instrument. On the basis of the level needed, it is convenient to categorize instruments into three groups: A, B, and C, as defined below. Examples of instruments in each group are provided. Note that the list of instruments provided here is for illustration only and is not meant to be exhaustive. It does not provide the exact category for an instrument at a user site. That category should be determined by users for their specific instruments or applications.

The exact grouping of an instrument must be determined by users for their specific requirements. Depending on individual user requirements, the same instrument may appropriately fall into one group for one user and another group for another user. Therefore, a careful selection of groups by users is highly encouraged.

##### Group A

Group A includes standard equipment with no measurement capability or usual requirement for calibration, where the manufacturer's specification of basic functionality is accepted as user requirements. Conformance of Group A equipment with user requirements may be verified and documented through visual observation of its operation. Examples of equipment in this group are nitrogen evaporators, magnetic stirrers, vortex mixers, and centrifuges.

##### Group B

Group B includes standard equipment and instruments providing measured values as well as equipment controlling physical parameters (such as temperature, pressure, or flow) that need calibration, where the user requirements are typically the same as the manufacturer's specification of functionality and operational limits. Conformance of Group B instruments or equipment to user requirements is determined according to the standard operating procedures for the instrument or equipment, and documented during IQ and OQ. Examples of instruments in this group are balances, melting point apparatus, light microscopes, pH meters, variable pipets, refractometers, thermometers, titrators, and viscosimeters. Examples of equipment in this group are muffle furnaces, ovens, refrigerator-freezers, water baths, pumps, and dilutors.

##### Group C

Group C includes instruments and computerized analytical systems, where user requirements for functionality, operational, and performance limits are specific for the analytical application. Conformance of Group C instruments to user requirements is determined by specific function tests and performance tests. Installing these instruments can be a complicated undertaking and may require the assistance of specialists. A full qualification process, as outlined in this document, should apply to these instruments. Examples of instruments in this group include the following:

- atomic absorption spectrometers
- differential scanning calorimeters
  - dissolution apparatus
  - electron microscopes
  - flame absorption spectrometers
- high-pressure liquid chromatographs
  - mass spectrometers
  - microplate readers
  - thermal gravimetric analyzers
- X-ray fluorescence spectrometers
- X-ray powder diffractometers
  - densitometers
  - diode-array detectors
  - elemental analyzers
  - gas chromatographs
    - IR spectrometers
    - near-IR spectrometers
    - Raman spectrometers

- UV/Vis spectrometers
- inductively coupled plasma-emission spectrometers

#### 1061 COLOR—INSTRUMENTAL MEASUREMENT

The observed color (see [631 Color and Achromicity](#)) of an object depends on the spectral energy of the illumination, the absorbing characteristics of the object, and the visual sensitivity of the observer over the visible range. Similarly, it is essential that any instrumental method that is widely applicable take these same factors into account.

Instrumental methods for measurement of color provide more objective data than the subjective viewing of colors by a small number of individuals. With adequate maintenance and calibration, instrumental methods can provide accurate and precise measurements of color and color differences that do not drift with time. The basis of any instrumental measurement of color is that the human eye has been shown to detect color via three "receptors." Hence, all colors can be broken down into a mixture of three radiant stimuli that are suitably chosen to excite all three receptors in the eye. Although no single set of real light sources can be used to match all colors (i.e., for any three lights chosen, some colors require a negative amount of one or more of the lights), three arbitrary stimuli have been defined, with which it is possible to define all real colors. Through extensive color-matching experiments with human subjects having normal color vision, distributing coefficients have been measured for each visible wavelength (400 nm to 700 nm) giving the relative amount of stimulation of each receptor caused by light of that wavelength. These distribution coefficients  $x$ ,  $y$ ,  $z$ , are shown below. Similarly, for any color the amount of stimulation of each receptor in the eye is defined by the set of Tristimulus values ( $X$ ,  $Y$ , and  $Z$ ) for that color.

The relationships between the distribution coefficient (see [accompanying figure](#)) and the tristimulus values are given in the equations

$$X = \int_0^{\infty} f_{\lambda} \bar{x}_{\lambda} P_{\lambda} d\lambda / Y',$$

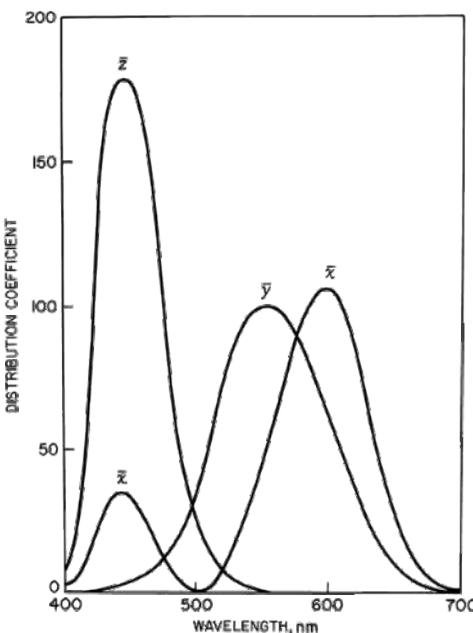

$$Y = \int_0^{\infty} f_{\lambda} \bar{y}_{\lambda} P_{\lambda} d\lambda / Y', \text{ and}$$

$$Z = \int_0^{\infty} f_{\lambda} \bar{z}_{\lambda} P_{\lambda} d\lambda / Y',$$

in which

$$Y' = \int_0^{\infty} f_{\lambda} P_{\lambda} d\lambda$$

is the spectral power of the illuminant, and  $f_{\lambda}$  is either the spectral reflectance ( $P_{\lambda}$ ) or spectral transmittance ( $T_{\lambda}$ ) of the material.

Distribution Coefficients from 400 to 700 nm

Once the tristimulus values of a color have been determined, they may be used to calculate the coordinates of the color in an idealized three-dimensional color space referred to as a visually uniform color space. Many sets of color equations have been developed in an attempt to define such a space. The equations given in this chapter represent a compromise between simplicity of calculation and conformance with ideality.

The coordinates of a color in a visually uniform color space may be used to calculate the deviation of a color from a chosen reference point. Where the instrumental method is used to determine the result of a test requiring color comparison of a test preparation with that of a standard or matching fluid, the parameter to be compared is the difference, in visually uniform color space, between the color of the blank and the color of the test specimen or standard.

#### Procedure

The considerations discussed under [Spectrophotometry and Light-Scattering](#) (851) apply to instrumental color measurement as well. In the spectrophotometric method, reflectance or transmittance values are obtained at discrete wavelengths throughout the visible spectrum, a band width of 10 nm or less being used. These values are then used to calculate the tristimulus values through the use of weighting factors.<sup>1</sup> In the colorimetric method, the weighting is performed through the use of filters.

In the measurement of the spectral reflectance of opaque solids, the angle of viewing is separated from the angle of illumination in such a manner that only rays reflected diffusely from the test specimen enter the receptor. Specular reflection and stray light are excluded.

For the measurement of the spectral transmittance of clear liquids, the specimen is irradiated from within 5 degrees of the normal to its surface, and the transmitted energy measured is that confined within 5 degrees from the normal. The color of solutions changes with the thickness of the layer measured. Unless special considerations dictate otherwise, a layer 1 cm thick should be used.

The methods described here are not applicable to hazy liquids or translucent solids.

#### calibration

For purposes of calibration, one of the following reference materials may be used, as required by instrument geometry. For transmittance measurements, purified water may be used as a white standard and assigned a transmittance of 1.000 at all wavelengths. Then the tristimulus values X, Y, and Z for CIE source C are 98.0, 100.0, and 118.1, respectively. For reflectance measurements, opaque porcelain plaques, whose calibration base is the perfect diffuse reflector and whose reflectance characteristics have been determined for the appropriate instrumental geometry, may be used.<sup>2</sup> If the geometry of sample presentation precludes the use of such plaques, pressed barium sulfate, white reflectance standard grade, may be used.<sup>3</sup>

After calibration with the above-mentioned materials, it is desirable whenever possible to measure a reference material as close to the color of the sample as possible. If a sample of the material being tested is not suitable for use as a long-term standard, color chips are available<sup>4</sup> which span the entire visually uniform color space in small increments. The use of such a reference standard is encouraged as a means of monitoring instrument performance even for absolute color determinations.

#### spectrophotometric method

Determine the reflectance or transmittance from 380 to 770 nm at intervals of 10 nm. Express the result as a percentage, the maximum being 100.0. Calculate the tristimulus values X, Y, and Z as follows.

Reflecting Materials— For reflecting materials the quantities X, Y, and Z are

$$\begin{aligned} X &= \sum_{380}^{770} \rho_\lambda \bar{x}_\lambda P_\lambda \Delta\lambda / Y', \\ Y &= \sum_{380}^{770} \rho_\lambda \bar{y}_\lambda P_\lambda \Delta\lambda / Y', \text{ and} \\ Z &= \sum_{380}^{770} \rho_\lambda \bar{z}_\lambda P_\lambda \Delta\lambda / Y' \end{aligned}$$

in which

$$Y' = \sum_{380}^{770} \bar{y}_\lambda P_\lambda \Delta\lambda, \rho_\lambda$$

is the spectral reflectance of the material,  $\bar{x}_\lambda P_\lambda$ ,  $\bar{y}_\lambda P_\lambda$ , and  $\bar{z}_\lambda P_\lambda$  are known values associated with each Standard Source, 1,2 and  $\Delta\lambda$  is expressed in nm.

Transmitting Materials— For transmitting materials, the quantities X, Y, and Z are calculated as above,  $\tau_\lambda$  (spectral transmittance) being substituted for  $\rho_\lambda$ .

#### colorimetric method

Operate a suitable colorimeter<sup>5</sup> to obtain values equivalent to the tristimulus values, X, Y, and Z. The accuracy with which the results obtained from the filter colorimeter match the tristimulus values may be indicated by determining the tristimulus values of plaques of strongly saturated colors and comparing these values with those computed from spectral measurements on a spectrophotometer.

#### Interpretation

##### color coordinates

The Color Coordinates, L\*, a\*, and b\* are defined by

$$\begin{aligned} L^* &= 116 (Y/Y_o)^{1/3} - 16, \\ a^* &= 500 [(X/X_o)^{1/3} - (Y/Y_o)^{1/3}], \text{ and} \\ b^* &= 200 [(Y/Y_o)^{1/3} - (Z/Z_o)^{1/3}] \end{aligned}$$

in which X<sub>o</sub>, Y<sub>o</sub>, and Z<sub>o</sub> are the tristimulus values of the nominally white or colorless standard, and Y/Y<sub>o</sub> > 0.01. Usually they are equal to the tristimulus values of the standard illuminant, with Y<sub>o</sub> set equal to 100.0. In this case X<sub>o</sub> = 98.0 and Z<sub>o</sub> = 118.1.

#### color difference

The total Color Difference ΔE\* is

$$\Delta E^* = [(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2]^{1/2}$$

in which ΔL\*, Δa\*, and Δb\* are the differences in color coordinates of the specimens being compared.

Instrumental variables can influence results. Although reliable comparisons can be made between similar colors measured concomitantly, results obtained on different instruments or under different operating conditions should be compared with caution. If it is necessary to compare data obtained from different instruments or taken at different times, etc., it is very helpful to have concomitant data obtained on a standard reference material such as color chips for opaque materials. Comparison of the readings on the reference material helps to identify variations caused by instrument performance.

1 Typical weighting factors are given by ASTM Z58.7.1-1951 as reported in the Journal of the Optical Society of America, Vol. 41, 1951, pages 431-439.

2 Suitable items are available from BYK-Gardner USA, 2431 Linden Lane, Silver Spring, MD 20910, or from Hunter Associates Laboratory, Inc., 11491 Sunset Hills Road, Reston, VA 22090.

3 Suitable material is available from Eastman Kodak Company, Rochester, NY 14650, as "White Reflectance Standard."

4 Centroid Color Charts may be obtained from suppliers of instruments for measurement of color.

5 A suitable tristimulus colorimeter is available from BYK-Gardner USA, 2431 Linden Lane, Silver Spring, MD 20910, or from Hunter Associates Laboratory, Inc., 11491 Sunset Hills Road, Reston, VA 22090.

1065 ION CHROMATOGRAPHY

## INTRODUCTION

Ion chromatography (IC) is a high-performance liquid chromatography (HPLC) instrumental technique used in USP test procedures such as identification tests and assays to measure inorganic anions and cations, organic acids, carbohydrates, sugar alcohols, aminoglycosides, amino acids, proteins, glycoproteins, and potentially other analytes.

As dictated by the nature of the analyte, IC has been applied to all aspects of the manufacturing and disposition of pharmaceutical products, including characterization of active ingredients, excipients, degradation products, impurities, and process streams. The following sample types are among those that have been analyzed: raw materials, intermediates (including media and culture broths), bulk active ingredients, diluents, formulated products, production equipment cleaning solutions, and waste streams. The technique is especially valuable for ionic or ionizable (in the mobile phase) analytes that have little or no native UV absorbance. The ability to couple the ion-exchange separation with numerous detection strategies, e.g., pulsed amperometric detection (PAD), expands IC applications to instances where analyte-specific detection strategies can provide the required degree of sensitivity or specificity. Utilization of such strategies allows IC applications to be implemented on appropriately configured HPLC systems. Additionally, ion-exclusion separations and pulsed amperometric detection expand the range of application of IC to aliphatic organic acids as well as to nonionic analytes of significant pharmaceutical interest including alcohols, alditols, carbohydrates, and amino acids. The wide dynamic range of the methodology makes it applicable for the quantification of trace contaminants as well as major product components.

Because IC typically uses dilute acids, alkalis, or salt solutions as the mobile phase, and does not use an organic solvent, IC does not require the purchase of costly organic solvents and hazardous disposal of the waste effluent. The effluent can be disposed of after appropriate neutralization (to ~pH 7) and, when necessary, after dilution with water.

IC allows separation using ion exchange, ion exclusion, or ion-pair approaches. IC separations are based on differences in charge density of the analyte species, which in turn depend on the valence and size of the individual ionic species to be measured. Separations are also performed on the basis of differences in the hydrophobic character of the ionic species. IC is typically performed at ambient temperature. As with other forms of HPLC, IC separations are based on varying capacity factors and typically follow the Knox equation. Ion chromatography is a technique complimentary to the more commonly used reversed-phase and normal-phase HPLC and to atomic absorption and ion-coupled plasma (plasma spectrochemistry) techniques in pharmaceutical analysis.

## APPARATUS

IC instruments closely resemble conventional HPLC instruments. Typical components include an autosampler, a high-pressure pump, an injection valve with a sample loop of suitable size (typically 10 to 250  $\mu$ L), a guard column, an analytical column, an optional suppressor or other forms of a post-column reaction system, a flow-through detector, and a data system ranging in complexity from an integrator to a computerized data system (Figure 1).

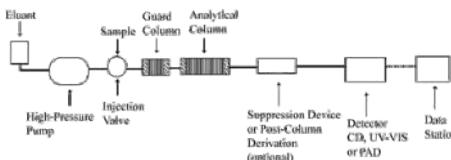

Figure 1. Components of a typical IC system illustrated schematically; CD = conductivity detector and PAD = pulsed amperometric detector.

Because mobile phases generally consist of dilute acids, alkalis, or salt solutions, the components in contact with the mobile phase and the sample are typically made from inert materials, such as polyetheretherketone. Conventional HPLC systems also may be used provided that their components are compatible with the mobile phase and injected sample solutions. A metal-free system should be used for trace metal analysis. Following suitable preparation, the sample is introduced via the injection valve. After the optional chemical suppression or other post-column reaction on the column effluent, the analyte species are detected using conductivity, amperometry, UV/VIS, or other detection modes. Because IC uses a predominantly ionic mobile phase, a suppressor is often necessary prior to conductometric detection, although nonsuppressed conductometric detection has been successfully used in pharmaceutical analysis.

### Stationary and Mobile Phases

As IC has developed and matured as an instrumental technique, the number of ion-exchange materials developed for IC has increased, facilitated by the understanding of the processes taking place at the surface of the stationary phase. In contrast to the silica-based column packing prevalent in classical HPLC, organic polymers are predominately used as support materials for IC. Such materials have a higher stability with respect to extremes in pH and in many cases are compatible with organic solvents. Typically, separation of anions requires the use of polymer-based anion exchangers and dilute bases as mobile phases. However, for cation separations, the stability over the entire pH range that is typical of organic polymers is not necessary, because dilute acids serve as mobile phases. Therefore, silica-based cation exchangers that exhibit a significantly higher chromatographic efficiency are commonly used for the separation of cations.

Depending on the separation mode (ion exchange, ion exclusion, or ion-pair), different types of stationary phases are used. For ion exchange, the stationary phase is either an anion or a cation exchanger. Typically, a strong cation exchanger is used for the ion-exclusion separation of organic acids, and a reversed-phase stationary phase is used when ion-pair is the separation mode. The ion-exchange capacity of a resin is defined as the number of ion-exchange sites per weight equivalent of the column packing and is typically expressed in terms of mEq per g of resin. With ion exchange, the retention times for the analyte ions increase with increasing ion-exchange capacity of the resin. This effect can be partly compensated for by using mobile phases of higher ionic strength. Styrene/divinylbenzene copolymers, polymethacrylate, and polyvinyl resins are the substrate materials used in the manufacturing process of the polymer-based ion exchangers. Organic polymers are functionalized directly at their surface, with the exception of latex-based ion exchangers, where the totally porous latex particle acts as an ion-exchange material. Surface-functionalized, "pellicular" substrates show a much higher chromatographic efficiency compared with the fully functionalized resins.

With ion exchange, a mobile phase consisting of mono- or divalent ionic species, alone or mixed at an optimum ratio, is used to accomplish the separation. In ion-exclusion methods,

particularly for organic acids, the mobile phase consists of mineral acids to maintain organic acids in their undissociated forms. Often, the nature of the analyte dictates the mobile phase and the detection mode used. Typical mobile phases used in IC are described below in the section on detectors.

#### Detectors

Conductivity detection is by far the most commonly employed mode of detection in IC. Although the original IC development work included the use of low-capacity ion-exchange resins for efficient chromatographic separation and conductometric detection of ions in a chemically suppressed mobile phase, the advances in column technologies as well as instrumentation development allow the use of high-capacity ion exchange today.

In suppressed IC, the background conductance of the ionic mobile phase is significantly reduced as it flows through the suppression device. For example, dilute NaOH, about 10 to 50 mM, used as the mobile phase in IC of anions is converted to H<sub>2</sub>O (poor conductivity) when the column effluent containing NaOH flows through a suppressor device present in an acidic form. The analyte ionic species in the column effluent are converted from their sodium or other metal salt forms to highly conducting acid forms (due to higher equivalent conductance of hydrogen ions compared to other cations). Analogous reactions occur in the hydroxide form suppressor in IC of cations, wherein the acidic mobile phase is converted to water, and the analyte cations are converted to highly conducting hydroxide forms (due to higher equivalent conductance of hydroxide ions compared to other anions).

The reduced background conductance and the enhanced signal due to the ionic species result in an enhanced signal-to-noise ratio for the conductometric detection of ions in suppressed IC. This results in reduced background noise and increasing sensitivity and reproducibility of the analysis. The commonly used chemical suppression devices fall into three broad categories. In the first type, the reactions occur across an ion-exchange membrane with the regenerant ions furnished by either a chemical or as products of electrolysis of water. In the second type, the suppression reactions occur in a packed bed of high-exchange capacity resin material, with regeneration either by a chemical or by electrolysis of water. In the third type, although not commonly used, the suppression reactions occur as the eluent stream mixes with the flowing stream of high-capacity resin material.

For pharmaceutical analyses, suppressed conductometric detection may be used for detection of trace ions in high purity waters. The commonly used mobile phases for the separation of anions by suppressed IC include hydroxide ions or a mixture of bicarbonate and carbonate ions. The common mobile phases for separation of cations usually consist of mineral acids or methanesulfonic acid.

Ion-chromatographic analyses also can be performed without chemical suppression, in which case the analytical column effluent flows directly to a conductivity detector. The typical eluents used in nonsuppressed IC are phthalic acid and p-hydroxybenzoic acid for the determination of anions and methanesulfonic acid for the determination of cations. The equivalent conductance values of chloride, sulfate, and other common anions are significantly greater than that of the eluent anion, and therefore, a positive peak is detected as the anions are carried through the detector. The equivalent conductance values of sodium, potassium, calcium, magnesium, and other common cations are significantly lower than that of the cation (H<sup>+</sup>) in the eluent. In this instance, a negative peak is detected as the cations are carried through the detector.

Nonsuppressed IC is easier to perform, and it is a useful technique for determining ions of weak acids such as cyanide and sulfide, which are nonconductive after chemical suppression but show a higher baseline noise. Pharmaceutical analyses can be performed in the nonsuppressed mode because the quantification limits are usually in the upper mg per L to low percentage levels. While suppressor-based methodologies must often be implemented on the instrument systems specifically designed for this purpose, IC may be performed without the suppressor on an existing HPLC. This is possible because the commonly used eluents in IC include dilute bases or acids that are compatible for use on existing HPLC instruments. When this approach is considered, analysts are encouraged to consult the instrument manufacturer for applicability of the instrument for the IC analysis.

#### other detectors

Other commonly used detection modes in IC include pulsed amperometry, direct UV detection, or post-column derivatization followed by UV/VIS detection.

**Pulsed Amperometric Detection Mode (PAD)**— PAD uses a specialized mode of the conventional amperometric technique. This type of detector is commonly used for the detection of electroactive species, e.g., organic compounds such as carbohydrates, sugar alcohols, amino acids, and organic sulfur species. In PAD, analytes are detected by an oxidative desorption process at the surface of an electrode located in the column effluent stream. Following the detection process, a series of potentials are applied for fixed time periods to clean the electrode surface. Unlike conventional amperometry that suffers from electrode surface fouling, a rapidly repeating sequence of different working potentials, referred to as waveform, helps the removal of the products of redox reactions from the electrode surface.

**Direct and Indirect UV Detection**— Direct UV Detection is used for inorganic and organic ions that possess a UV chromophore. These include organic acids, bromide, iodide, nitrate, nitrite, thiosulfate, and cyano-metal complexes. Analogous to the inverse conductometric detection of cations, UV detection may also be performed indirectly. This method is called indirect photometric chromatography (IPC).

**Photometric Detection**— Photometric detection involves chelation of the metal ions in column effluent with a color-forming reagent prior to detection with a visible wavelength. A classic example is the separation of metal ions in which the column effluent is chelated with 4-(2-pyridylazo)-resorcinol followed by detection at 510 to 530 nm.

#### SAMPLE PREPARATION

Typically sample preparation for IC includes dilution or filtering through a 0.45-μm filter, or both. Under certain circumstances, samples may require removal of undesirable species through solid-phase extraction (SPE) techniques. For example, a highly alkaline sample can be neutralized by having it pass through an SPE cartridge packed with cation-exchange material in the acidic form.

#### PROCEDURE

Conductometric detection requires high purity water (generally, resistivity greater than 18 megohm-cm) and high-purity chemicals for the preparation of the mobile phase. For ion-pair separation with UV detection, water and mobile phase components of low UV absorbance should be used.

For ion exchange, the retention time of ions increases with a decrease in the ionic strength and valency (charge) of the mobile phase components. For example, at equimolar concentrations of sodium hydroxide or sodium carbonate mobile phase, capacity factors (k') for anions are smaller with sodium hydroxide as the mobile phase than with sodium carbonate as the mobile phase. Some mobile phases, such as sodium hydroxide, can absorb ambient carbon dioxide, resulting in its composition change and often in baseline artifacts. In this instance, care should be taken to prevent absorption of carbon dioxide by the sodium hydroxide mobile phase.

For ion exclusion, capacity factors of organic acids increase with an increase in ionic strength or concentration of mineral acids but decrease with the increase of the column temperature. Because permeation volume remains constant, these effects are usually small. Addition of a solvent such as acetonitrile shortens the retention of organic acids.

Like other HPLC techniques, IC systems are calibrated by plotting peak responses in comparison with known concentrations of a reference standard, using either an external or internal standardization procedure.

USP32-NF27 Page 514

Pharmacopeial Forum: Volume No. 32(3) Page 899

#### 1070 EMERGENCY MEDICAL SERVICES VEHICLES AND AMBULANCES—STORAGE OF PREPARATIONS

The storage and handling of pharmaceuticals in emergency vehicles and ambulances should be done so that the attributes of the official articles are preserved. There are a number of practices that need consideration when an effective plan is formulated, evaluated, put in place, and periodically re-evaluated. Those practices are listed here.

Monitoring devices should be in place to record weekly temperatures, and allow the calculation of mean kinetic temperature (MKT) for conformance to controlled room temperature storage for those vehicles utilized continuously. Measurement should also be made during a typical challenging 24-hour period, and the derived temperature should be used for the calculation of MKT and storage temperature of the sample.

#### PHARMACEUTICAL STORAGE CABINET MONITORING; LOCATION OF PARKED VEHICLES

Ambulances and other emergency medical response vehicles that routinely carry Pharmacopeial articles should be monitored to verify that temperature profiles and onboard pharmaceutical storage cabinets or cold chests are within established limits. Suitable monitoring devices are to be placed in the pharmaceutical cabinet of each vehicle that records highest and lowest temperatures, at the least, of each hot summer and cold winter day. To avoid temperature extremes, ambulance personnel should consider parking in the shade or in air-conditioned garages in the summer or in heated garages in the winter.

#### STOCK ROTATION

A program of regular stock rotation should be in place for articles with low rates of turnover. Rotation is understood as transfer of the articles with suitable marking of stock items to an appropriate climate controlled facility or storage cabinet such as in an ambulance bay. Off-vehicle storage of each article is subject to the storage requirement in the approved labeling or the pertinent USP monograph.

#### PORTABLE CARRYING CASE STORAGE AND MONITORING

The portable bag or carrying case in which drugs are kept is to be insulated, and when not in use, should be kept in a pharmaceutical storage cabinet or at controlled room temperature within facilities. Storage in portable bags or cases only, rather than in onboard cabinets, should be considered to facilitate stock rotation where indicated. The use of time-temperature indicators is recommended to monitor cumulative insult to the contents of all compartments.

#### ADDITIONAL REQUIREMENTS FOR SOME ARTICLES

All articles are to be protected from excessive heat (40°). If the article requires storage in a cold or dry place or at controlled room temperature, then suitable measures are to be taken to maintain it within the defined limits (see Preservation, Packaging, Storage, and Labeling under General Notices and Requirements.) Articles that have the most stringent storage requirements determine the storage of mixed loads.

#### STORAGE AND HANDLING OF SENSITIVE PREPARATIONS

Environmentally sensitive preparations are not to be stored in emergency response vehicles unless the onboard cabinet in which the medications is stored is climate controlled or a time-temperature indicator is attached to each package. If environmentally sensitive preparations must be kept in the emergency medical services vehicle, then the supply of medications should be rotated with reserve stock on a schedule based on local climate, but not longer than every 3 days.

#### USE OF TIME-TEMPERATURE INDICATORS

Attach time-temperature indicators to individual thermally sensitive preparations where time outside of the onboard cabinet can exceed 4 days total. Onboard cabinets must be insulated and while medications are inside, active heating and cooling devices should be used in accord with the local climate and as specified for the preparations.

1072 DISINFECTANTS AND ANTISEPTICS

#### INTRODUCTION

A sound cleaning and sanitization program is needed for controlled environments used in the manufacture of Pharmacopeial articles to prevent the microbial contamination of these articles. Sterile drug products may be contaminated via their pharmaceutical ingredients, process water, packaging components, manufacturing environment, processing equipment, and manufacturing operators. Current Good Manufacturing Practices (cGMPs) emphasize the size, design, construction, and location of buildings and construction materials, and the appropriate material flow to facilitate cleaning, maintenance, and proper operations for the manufacture of drug products. When disinfectants are used in a manufacturing environment, care should be taken to prevent the drug product from becoming contaminated with chemical disinfectants as a result of the inherent toxicity of the disinfectants. The requirements for aseptic processing include readily cleanable floors, walls, and ceilings that have smooth and nonporous surfaces; particulate, temperature, and humidity controls; and cleaning and disinfecting procedures to produce and maintain aseptic conditions. The cleaning and sanitization program should achieve specified cleanliness standards, control microbial contamination of products, and be designed to prevent the chemical contamination of pharmaceutical ingredients, product-contact surfaces and/or equipment, packaging materials, and ultimately the drug products. These principles also apply to nonsterile dosage forms where the microbial contamination is controlled by the selection of appropriate pharmaceutical ingredients, utilities, manufacturing environments, sound equipment cleaning procedures, products especially formulated to control water activity, inclusion of suitable preservatives, and product packaging design.

In addition to disinfectants, antiseptics are used to decontaminate human skin and exposed tissue and may be used by personnel prior to entering the manufacturing area. Chemical sterilants may be used to decontaminate surfaces in manufacturing and sterility testing areas. Furthermore, sterilants may be used for the sterilization of Pharmacopeial articles, and UV irradiation may be used as a surface sanitizer.

This general information chapter will discuss the selection of suitable chemical disinfectants and antiseptics; the demonstration of their bactericidal, fungicidal, and sporicidal efficacy; the application of disinfectants in the sterile pharmaceutical manufacturing area; and regulation and safety considerations. Biofilm formation and its relationship to disinfectants are outside the scope of this chapter. Additional information not covered in the chapter may be obtained from standard texts on disinfectants and antiseptics.<sup>1</sup>

#### DEFINITIONS

Antiseptic—An agent that inhibits or destroys microorganisms on living tissue including skin, oral cavities, and open wounds.

Chemical Disinfectant—A chemical agent used on inanimate surfaces and objects to destroy infectious fungi, viruses, and bacteria, but not necessarily their spores. Sporicidal and antiviral agents may be considered a special class of disinfectants. Disinfectants are often categorized as high-level, intermediate-level, and low-level by medically oriented groups based upon their efficacy against various microorganisms.

Cleaning Agent—An agent for the removal from facility and equipment surfaces of product residues that may inactivate sanitizing agents or harbor microorganisms.

Decontamination—The removal of microorganisms by disinfection or sterilization.

Disinfectant—A chemical or physical agent that destroys or removes vegetative forms of harmful microorganisms when applied to a surface.

Sanitizing Agent—An agent for reducing, on inanimate surfaces, the number of all forms of microbial life including fungi, viruses, and bacteria.

Sporicidal Agent—An agent that destroys bacterial and fungal spores when used in sufficient concentration for a specified contact time. It is expected to kill all vegetative microorganisms.

Sterilant—An agent that destroys all forms of microbial life including fungi, viruses, and all forms of bacteria and their spores. Sterilants are liquid or vapor-phase agents.

Microorganisms differ greatly in their resistance to disinfection agents. The order of resistance of clinically significant microorganisms to chemical disinfectants from most to least resistant is listed in [Table 1](#).

Table 1. The Resistance of Some Clinically Important Microorganisms to Chemical Disinfectants (Listed in Order of Decreasing Resistance)

Type of Microorganisms	Examples
Bacterial spores	Bacillus subtilis and Clostridium sporogenes
Mycobacteria	Mycobacterium tuberculosis
Nonlipid-coated viruses	Poliiovirus and rhinovirus
Fungal spores and vegetative molds and yeast	Trichophyton, Cryptococcus, and Candida spp.
Vegetative bacteria	Pseudomonas aeruginosa, Staphylococcus aureus, and Salmonella spp.
Lipid-coated viruses	Herpes simplex virus, hepatitis B virus, and human immunodeficiency virus

#### CLASSIFICATION OF DISINFECTANTS

Chemical disinfectants are classified by their chemical type. This includes aldehydes, alcohols, halogens, peroxides, quaternary ammonium compounds, and phenolic compounds (see [Table 2](#)).

Table 2. General Classification of Antiseptics, Disinfectants, and Sporicidal Agents

Chemical Entity	Classification	Example
Aldehydes	Sporicidal agent	2% Glutaraldehyde
Alcohols	General purpose disinfectant, antiseptic, antiviral agent	70% Isopropyl alcohol, 70% alcohol
Chlorine and sodium hypochlorite	Sporicidal agent	0.5% Sodium hypochlorite
Phenolics	General purpose disinfectant	500 µg per g Chlor cresol, 500 µg per g chloroxylenol
Ozone	Sporicidal agent	8% Gas by weight
Hydrogen peroxide	Vapor phase sterilant, liquid sporicidal agent, antiseptic	4 µg per g H2O2 vapor, 10%–25% solution, 3% solution
Substituted diguanides	Antiseptic agent	0.5% Chlorhexidine gluconate
Peracetic acid	Liquid sterilant, vapor phase sterilant	0.2% Peracetic acid, 1 µg per g peracetic acid
Ethylene oxide	Vapor-phase sterilant	600 µg per g Ethylene oxide
Quaternary ammonium compounds	General purpose disinfectant, antiseptic	200 µg per g Benzalkonium chloride
$\beta$ -Propiolactone	Sporicidal agent	100 µg per g $\beta$ -Propiolactone

The effectiveness of a disinfectant depends on its intrinsic biocidal activity, the concentration of the disinfectant, the contact time, the nature of the surface disinfected, the hardness of water used to dilute the disinfectant, the amount of organic materials present on the surface, and the type and the number of microorganisms present. Under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), the Environmental Protection Agency (EPA) registers chemical disinfectants marketed in the United States and requires manufacturers to supply product information on the use dilution, type of microorganisms killed, and the necessary contact time. Certain liquid chemical sterilizers intended for use on critical or semicritical medical devices are defined and regulated by the U.S. Food and Drug Administration (FDA).

#### SELECTION OF AN ANTISEPTIC FOR HAND AND SURGICAL SITE DISINFECTION

Hands and surgical sites are disinfected in a hospital setting to reduce the resident flora and to remove transient flora (e.g., *Streptococcus pyogenes*) and methicillin-resistant *S. aureus* and *P. aeruginosa* that have been implicated in hospital-associated infection. Use of antiseptics to disinfect hands has been shown to be more effective than soap and water in reducing the counts of bacteria on the skin; repeated antiseptic use further reduces these counts. These principles may be applied to clean-room operators in the pharmaceutical industry.

Common antiseptics include 4% chlorhexidine, 10% povidone-iodine, 3% hexachlorophene, 70% isopropyl alcohol, and 0.5% chlorhexidine in 95% alcohol.

#### SELECTION OF A DISINFECTANT FOR USE IN A PHARMACEUTICAL MANUFACTURING ENVIRONMENT

When selecting a disinfectant for use in a pharmaceutical manufacturing area, the following points should be considered: the number and types of microorganisms to be controlled; the spectrum of activity of commercially available disinfectants; the reputation of the disinfectant supplier; the claims as a sterilant; the disinfectant or sanitizer supported by the EPA registrations; the concentration, application method, and contact time of the disinfectant; the nature of the surface material being disinfected and its compatibility with the disinfectant; the amount of organic compounds on the surface that may inactivate a disinfectant; the possible need to maintain a residual bactericidal activity of the disinfectant on the surface; the corrosiveness of the disinfectant to equipment with repeated application; the safety considerations for operators applying the disinfectant; the compatibility of the disinfectant with cleaning agents and other disinfectants; the planned disinfectant rotation; and the steps that need to be taken to avoid the contamination of pharmaceutical products by a disinfectant.<sup>2</sup>

#### THEORETICAL DISCUSSION OF DISINFECTANT ACTIVITY

Plots of the log of the number of microorganisms per mL surviving in a disinfectant solution indicate that first-order kinetics can be applied as a gross approximation to the reduction in microbial count with respect to time. In practice, the plots show a more sigmoid curve with a slower initial reduction in numbers followed by an increasing rate with respect to time.

The rate constant, K, for the disinfection process can be calculated by the formula:

$$(1 / t)(\log NO / N)$$

in which t is the time, in minutes, for the microbial count to be reduced from NO to N; NO is the initial number of organisms, in cfu per mL; and N is the final number, in cfu per mL, of organisms.

As with a first-order chemical reaction, the same concentration of disinfectant reduces the number of organisms more rapidly at elevated temperatures. This can be expressed as a

temperature, T, coefficient per  $10^{\circ}$  rise in temperature, Q10, calculated by the formula:

$$\text{Time to decontamination at } T^{\circ} / \text{Time to decontamination at } T$$

$$\text{in which } T \text{ is } T^{\circ} - 10.$$

Further evidence that a first-order reaction is an inadequate description of disinfection is that the Q10 values for chemical and enzyme reactions are 2 to 3, while the common disinfectants phenol and alcohol have a Q10 of 4 and 45, respectively.

Critical to the successful employment of disinfectants is an understanding of the effect of disinfectant concentration on microbial reduction. A plot of the log of the time to reduce the microbial population in a standard inoculum to zero against the log of the disinfectant concentration is a straight line with the slope of the line termed the concentration exponent, n. The relationship can be expressed as follows:

$$n = (\log \text{ of the kill time at concentration } C_2) - (\log \text{ of the kill time at concentration } C_1) / (\log C_1 - \log C_2)$$

in which C1 and C2 are the higher and lower disinfectant concentrations, respectively.

The wide differences in concentration exponents, n, have practical consequences in picking the use dilution of different disinfectants and in using dilution to neutralize a disinfectant in disinfectant-effectiveness testing and routine microbial monitoring of the manufacturing environment. For example, mercuric chloride has a concentration exponent of 1, so a 3-fold dilution will reduce the disinfectant activity by 31 (or by one-third), while phenol with a concentration exponent of 6 will have a 36 (or a 729-fold) reduction in disinfectant activity. Disinfectants with a larger concentration exponent or dilution coefficient rapidly lose activity when diluted. The concentration exponents for some disinfectants are listed in [Table 3](#).

Table 3. Concentration Exponents of Common Antiseptics, Disinfectants, and Sterilants

Disinfectant	Concentration Exponents
Hydrogen peroxide	0.5
Sodium hypochlorite	0.5
Mercuric chloride	1
Chlorhexidine	2
Formaldehyde	1
Alcohol	9
Phenol	6
Quaternary ammonium compounds	0.8 to 2.5
Aliphatic alcohols	6.0 to 12.7
Phenolic compounds	4 to 9.9

Another important consideration may be the pH of the disinfectant. Many disinfectants are more active in the ionized form, while others are more active in the nonionized form. The degree of ionization will depend on the pKa of the agent and the pH of the disinfection environment. For example, phenol, with a pKa of 10, will be more effective at a pH below 7 where it is nonionized, while acetic acid will be more effective at a pH below 4 where it is ionized.

#### MECHANISM OF DISINFECTANT ACTIVITY

[Table 4](#) lists the sites and modes of action of some representative disinfectants.

Table 4. Mechanism of Disinfectant Activity Against Microbial Cells

Target	Disinfectant
Cell wall	Formaldehyde, hypochlorite, and mercurials
Cytoplasmic membrane, action on membrane potential	Anilides and hexachlorophene
Membrane enzymes, action on electron-transport chain	Hexachlorophene
Action on ATP	Chlorhexidine and ethylene oxide
Action on enzymes with -SH groups	Ethylene oxide, glutaraldehyde, hydrogen peroxide, hypochlorite, iodine, and mercurials
Action on general membrane permeability	Alcohols, chlorhexidine, and quaternary ammonium compounds
Cell contents, general coagulation	Chlorhexidine, aldehydes, hexachlorophene, and quaternary ammonium compounds
Ribosomes	Hydrogen peroxide and mercurials
Nucleic acids	Hypochlorites
Thiol groups	Ethylene oxide, glutaraldehyde, hydrogen peroxide, hypochlorite, mercurials
Amino groups	Ethylene oxide, glutaraldehyde, and hypochlorite
General oxidation	Ethylene oxide, glutaraldehyde, and hypochlorite

#### MICROBIAL RESISTANCE TO DISINFECTANTS

The development of microbial resistance to antibiotics is a well-described phenomenon. The development of microbial resistance to disinfectants is less likely, as disinfectants are more powerful biocidal agents than antibiotics and are applied in high concentrations against low populations of microorganisms usually not growing actively, so the selective pressure for the development of resistance is less profound. However, the most frequently isolated microorganisms from an environmental monitoring program may be periodically subjected to use dilution testing with the agents used in the disinfection program to confirm their susceptibility.

#### DISINFECTANT CHALLENGE TESTING

Under FIFRA, the EPA requires companies that register public health antimicrobial pesticide products including disinfectants, sanitization agents, sporicidal agents, and sterilants to ensure the safety and effectiveness of their products before they are sold or distributed. Companies registering these products must address the chemical composition of their product, include toxicology data to document that their product is safe if used as directed on the label, include efficacy data to document their claims of effectiveness against specific organisms and to support the directions for use provided in the labeling, and provide labeling that reflects the required elements for safe and effective use. While these directions provide valuable information, they may not be helpful in terms of the products' use as disinfectants in a manufacturing environment.

In the United States, the official disinfectant testing methods are published by AOAC International<sup>3</sup> and include the Phenol-Coefficient Test, Use-Dilution Method Test, Hard Surface Carrier Method, and Sporicidal Carrier Test. A scientific study submitted for EPA review in support of disinfectant registration must be conducted at a laboratory facility that follows the Good Laboratory Practices (GLP) regulations (21 CFR 58). To demonstrate the efficacy of a disinfectant within a pharmaceutical manufacturing environment, it may be deemed necessary to conduct the following tests: (1) use-dilution tests (screening disinfectants for their efficacy at various concentrations and contact times against a wide range of standard test organisms and environmental isolates); (2) surface challenge tests (using standard test microorganisms and microorganisms that are typical environmental isolates, applying

disinfectants to surfaces at the selected use concentration with a specified contact time, and determining the log reduction of the challenge microorganisms); and (3) a statistical comparison of the frequency of isolation and numbers of microorganisms isolated prior to and after the implementation of a new disinfectant. This is considered necessary because critical process steps like disinfection of aseptic processing areas, as required by GMP regulations, need to be validated, and the EPA registration requirements do not address how disinfectants are used in the pharmaceutical, biotechnology, and medical device industries. For the surface challenge tests, the test organisms are enumerated using swabs, surface rinse, or contact plate methods. Neutralizers that inactivate the disinfectants should be included in either the diluent or microbiological media used for microbial enumeration or both

(see [Table 5](#)). Additional information on disinfectant neutralization may be found in [Validation of Microbial Recovery from Pharmacopeial Articles](#) (1227).

Table 5. Neutralizing Agents for Common Disinfectants

Disinfectant	Neutralizing Agent
Alcohols	Dilution or polysorbate 80
Glutaraldehyde	Glycine and sodium bisulfite
Sodium hypochlorite	Sodium thiosulfate
Chlorhexidine	Polysorbate 80 and lecithin
Mercuric chloride and other mercurials	Thioglycolic acid
Quaternary ammonium compounds	Polysorbate 80 and lecithin
Phenolic compounds	Dilution or polysorbate 80 and lecithin

Universal neutralizer broths may be formulated to contain a range of neutralizing agents. For example, Dey/Engley (D/E) broth contains 0.5% polysorbate 80, 0.7% lecithin, 0.1% sodium thioglycolate, 0.6% sodium thiosulfate, 0.25% sodium bisulfite, 0.5% tryptone, 0.25% yeast extract, and 1.0% dextrose; Itephen broth contains 0.5% polysorbate 80, 0.07% lecithin, 1.0% peptamin, 0.5% beef extract, and 0.5% sodium chloride; and Tryptone-Azolectin-Tween (TAT) broth base + tween 20 contains 4.0% (v/v) polysorbate 20, 0.5% lecithin, and 2.0% tryptone.

In practice, sufficient organisms need to be inoculated on a 2-inch × 2-inch square of the surface being decontaminated, i.e., a coupon, to demonstrate at least a 2 (for bacterial spores) to 3 (for vegetative bacteria) log reduction during a predetermined contact time (i.e., 10 minutes or above the recovery observed with a control disinfectant application). The efficacy of the neutralizers and their ability to recover inoculated microorganisms from the material should be demonstrated during the use-dilution or surface-challenge studies. Points to remember are that disinfectants are less effective against the higher numbers of microorganisms used in laboratory challenge tests than they are against the numbers that are found in clean rooms (see [Microbiological Evaluation of Clean Rooms and Other Controlled Environments](#) (1116)); that inocula from the log growth phase that are typically employed in laboratory tests are more resistant, with the exception of spores formed during the static phase, than those from a static or dying culture or stressed organisms in the environment; and that microorganisms may be physically removed during actual disinfectant application in the manufacturing area.

Although not all inclusive, typical challenge organisms that may be employed are listed in [Table 6](#).

Table 6. Typical Challenge Organisms

AOAC Challenge Organisms	Typical Environmental Isolates
Bactericide: Escherichia coli, ATCC 11229; S. aureus, ATCC 6538; P. aeruginosa, ATCC 15442	Bactericide: Micrococcus luteus, S. epidermidis, <i>Corynebacterium jeikeium</i> , <i>P. vesiculans</i>
Fungicide: C. albicans, ATCC 10231 or 2091; Penicillium chrysogenum, ATCC 11709; Aspergillus niger, ATCC 16404	Fungicide: <i>P. chrysogenum</i> , <i>A. niger</i>
Sporicide: <i>B. subtilis</i> , ATCC 19659	Sporicide: <i>B. sphaericus</i> , <i>B. thuringiensis</i>

Because a wide range of different materials of construction are used in clean rooms and other controlled areas, each material needs to be evaluated separately to validate the efficacy of a given disinfectant. [Table 7](#) contains a list of common materials used in clean room construction.

Table 7. Typical Surfaces to be Decontaminated by Disinfectants in a Pharmaceutical Manufacturing Area

Material	Application
Stainless steel 304L and 316L grades	Work surfaces, filling equipment, and tanks
Glass	Windows and vessels
Plastic, vinyl	Curtains
Plastic, polycarbonate	Insulation coating
Lexan® (plexiglass)	Shields
Epoxy-coated gypsum	Walls and ceilings
Fiberglass-reinforced plastic	Wall paneling
Tyvek®	Equipment wraps
Terrazzo tiles	Floors

#### DISINFECTANTS IN A CLEANING AND SANITIZATION PROGRAM

The selection of suitable disinfectants and the verification of their effectiveness in surface challenge testing is critical in the development of a cleaning and sanitization program.

Issues associated with the successful implementation of such a program are the development of written procedures, staff training, decisions on disinfectant rotation, institution of application methods and contact times, environmental monitoring to demonstrate efficacy, and personnel safety.

The cGMP 21 CFR 211.67, Equipment Cleaning and Maintenance, details the requirements for written procedures for cleaning, maintenance, and sanitization of pharmaceutical manufacturing equipment. These procedures should address the assignment of responsibility, establishment of schedules, details of cleaning operations, protection of clean equipment prior to use, inspection for cleanliness immediately prior to use, and maintenance of cleaning and sanitization records.

Staff involved in disinfection require training in microbiology, industry practices for cleaning and sanitization, safe handling of concentrated disinfectants, the preparation and disposal of disinfectants, and appropriate application methods. It should be emphasized that the preparation of the correct dilutions is critical because many disinfectant failures can be attributed to use of disinfectant solutions that are too dilute. Typically disinfectants used in aseptic processing and filling areas are diluted with Sterile Purified Water, and are prepared aseptically. Alternately, the disinfectant may be diluted with Purified Water, and then sterile filtered to eliminate microorganisms that may potentially persist in a disinfectant. Diluted disinfectants must have an assigned expiration date justified by effectiveness studies.

Because it is theoretically possible that the selective pressure of the continuous use of a single disinfectant could result in the presence of disinfectant-resistant microorganisms in a manufacturing area, in some quarters the rotation of disinfectants has been advocated. However, the literature supports the belief that the exposure of low numbers of microorganisms on facility and equipment surfaces within a clean room where they are not actively proliferating will not result in the selective pressure that may be seen with the antibiotics. It is prudent to augment the daily use of a bactericidal disinfectant with weekly (or monthly) use of a sporicidal agent. The daily application of sporicidal agents is not generally favored because of their tendency to corrode equipment and because of the potential safety issues with chronic operator exposure. Other disinfection rotation schemes may be supported on the basis of a review of the historical environmental monitoring data. Disinfectants applied on potential product contact surfaces are typically removed with 70% alcohol wipes. The removal of

residual disinfectants should be monitored for effectiveness as a precaution against the possibility of product contamination.

The greatest safety concerns are in the handling of concentrated disinfectants and the mixing of incompatible disinfectants. For example, concentrated sodium hypochlorite solutions (at a concentration of more than 5%) are strong oxidants and will decompose on heating, on contact with acids, and under the influence of light, producing toxic and corrosive gases including chlorine. In contrast, dilute solutions (at a concentration of less than 0.5%) are not considered as hazardous. Under no circumstances should disinfectants of different concentrations be mixed. Material Safety Data Sheets for all the disinfectants used in a manufacturing area should be available to personnel handling these agents. Appropriate safety equipment such as face shields, safety glasses, gloves, and uniforms must be issued to personnel handling the disinfectant preparation, and personnel must be trained in the proper use of this equipment. Safety showers and eye wash stations must be situated in the work area where disinfectant solutions are prepared.

## 1074 EXCIPIENT BIOLOGICAL SAFETY EVALUATION GUIDELINES

### INTRODUCTION

This informational chapter presents a scientifically-based approach for the safety assessment of new pharmaceutical excipients (i.e., those excipients that have not been previously used or permitted for use in a pharmaceutical preparation). The guidelines presented herein provide a protocol for developing an adequate database upon which to establish conditions for the safe use of a new excipient intended for use in products administered by various dosage routes. [note—The final section of this chapter, [Definition of Terms](#), lists some terms referred to in this chapter.]

An excipient may perform a variety of functionality roles in a pharmaceutical product; but, unlike pharmacologically active drug entities, the excipient displays either no pharmacological activity or very limited and directed activity. Because of these differences between excipients and active drug substances in terms of risk and benefit relationships and expected biological activities, the approaches for safety assessments of excipients and active drug substances will differ. Therefore, it is important to note that the guidelines presented in this informational chapter apply only to the safety assessment of excipients, not to the safety assessment of active drug substances.

These testing guidelines are informational in nature and are intended to be used by professionals having a knowledge of toxicology and associated sciences. It is also intended that the applicable safety test method requirements of the receiving regulatory authority would be used in a proposal for market entry. For example, if a proposal is to be submitted to the U.S.

Food and Drug Administration, that agency's safety test requirements would have to be met. These guidelines do not provide specific details regarding test methodology and data interpretation. Test procedures that are generally recognized by experts and by the regulatory agencies should be used. Alternatives to the use of living animals are encouraged wherever these alternative procedures have been validated for the intended purpose and where it is known that the alternative procedure will provide sufficient data upon which to base a safety judgment. It is recommended that the Guiding Principles on the Use of Animals in Toxicology of the Society of Toxicology (1996) and, in other countries, the appropriate legal and professional codes, be adhered to in the conduct of all test procedures. All studies must meet the requirements of the appropriate national good laboratory practice guidelines in effect in the country where the studies are being conducted.

In cases of extensive human experience based upon food use, there may be sufficient information to fulfill the requirements of the guidelines for orally-ingested excipients only. In addition, there may be animal-based data, which was developed for other purposes, that may be used to fulfill the testing guidelines requirements. If the data requirements have been met through prior human use experience and pertinent human data have been collected in a scientifically sound manner, there is no need to provide animal data for those endpoints evaluated by prior clinical experience.

Some dosage routes offer unique toxicological challenges, and the guidelines include provisions for these routes (e.g., inhalation). Also, further explanation is provided regarding numbers of species and other basic information (e.g., two species, one rodent and one nonrodent).

The extent of information required to define a set of baseline data, which constitute a toxicological and chemical database, is dependent upon the intended use of, and duration of, dosing of the candidate excipient material. It is critical that a thorough review of background information be conducted before embarking on a testing regimen. In addition to literature database reviews, information should be obtained regarding the physical and chemical properties of the compound; its manufacturing process (or processes); and product specifications including limits of impurities, potential for pharmacological activity, exposure conditions (i.e., dose, duration, frequency of use, dosage formulation, and route of administration), and potential user population. Also, base toxicity information covering the topics is fundamental. Particular attention should be addressed to the absorption/distribution/metabolism/excretion/pharmacokinetics (ADME/PK) studies because much of the later decision process will be dependent upon these data.

These guidelines provide a mechanism for obtaining sets of baseline data for all candidate excipient materials. The background information and baseline toxicity information alone may support the use of the candidate excipient either in a short half-life product that is not administered in a frequency that results in a residual excipient build-up in body tissue or in a product used only once or twice in a lifetime, such as a diagnostic agent. Additional tests, listed under Step 4 of the Safety Assessment Guidelines, are necessary for candidate excipient material that is to be used in a manner that will result in short- or intermediate-term repeated exposure in humans—that is, a pharmaceutical product that will be administered for less than 10 days or for 30 to 90 consecutive days, respectively. For a candidate excipient material that is intended for use in a pharmaceutical product intended for either intermittent or chronic administration over a long time period, such as a treatment for psoriasis or an insulin preparation, further tests are required. These tests are listed under Step 7 of the guidelines and in the appropriate section under Additional Requirements for Specific Exposure Routes. While providing guidance for consumer safety, some of the required tests are intended to provide information to address occupational safety (e.g., skin and eye irritation).

The guidelines are summarized in [Table 1](#). Tests that are required (R) by the guidelines are distinct from those that are recommended conditionally (C). Whether conditional tests are conducted is dependent upon the conditions of use and available biological data. Consideration must also be given to the requirements of the regulatory authorities when making the decision to test.

Table 1. Summary of Excipient Guidelines

Tests	Routes of Exposure for Humans					
	Oral	Mucosal	Dermal/ Topical/ Trans- dermal	Injectable*	Inhalation/ Intranasal	Ocular
Baseline Toxicity Data						
Acute Oral Toxicity	R	R	R	R	R	R

Acute Dermal Toxicity	R	R	R	R	R	R
Acute Inhalation Toxicity	C	C	C	C	R	C
Eye Irritation	R	R	R	R	R	R
Skin Irritation	R	R	R	R	R	R
Skin Sensitization	R	R	R	R	R	R

**SAFETY ASSESSMENT GUIDELINES**
**Background Information**

Before proceeding to the steps under Data Requirements and Checkpoints, the following points should be reviewed and defined:

- Review literature information using all appropriate databases
  - Define chemical and physical properties
  - Define manufacturing process
- Define product specifications, including impurities and residual solvents (see applicable ICH guidelines)
  - Estimate exposure conditions (dose, duration, frequency route)
    - Define user population
    - Assess potential for pharmacologic activity.

At this point evaluate what is known, and develop the initial approach to testing.

**Data Requirements and Checkpoints**
**STEP 1: Toxicity Data (see Baseline Toxicity Data)**

The toxicity data should take into account the following information:

- Effects of acute exposure by oral and intended routes
- Effects of repeated exposures by intended routes
  - Effects of in vitro genotoxicity assays
- ADME/PK by oral or appropriate routes; single or multiple doses.

**STEP 2: Depending on results of above, evaluate effects of a single dose in humans.**

STEP 3: Checkpoint: Evaluate results of above and proposed exposure conditions and exposed population. The above data might allow use in a single product with a short half-life (e.g., a diagnostic agent).

**STEP 4: Gather the following additional data:**

- Effects of subchronic exposure in appropriate species and routes
- Embryo-fetal development studies via appropriate route of exposure
  - Additional in vitro and in vivo genotoxicity tests.

STEP 5: Depending on results of above, consideration should be given to testing in humans as part of the clinical trials of an active ingredient or as a stand-alone procedure.

STEP 6: Checkpoint: Evaluate all of above information. Data might allow use in a variety of products intended for short-term, repeated intake (e.g., an antibiotic). If the ADME/PK studies for a noninjectable excipient show no absorption, data may permit using a product for 30 to 90 consecutive days.

**STEP 7: Additional data should be obtained for use in a product taken chronically, either daily or intermittently, over a long time period depending on:**

- Results of subchronic studies and long-term toxicity in appropriate mammalian nonrodents
  - Reproductive toxicity studies
- Other test results and human exposure data and long-term toxicity or carcinogenicity in rodents.

**Baseline Toxicity Data**

The following data should be taken into account:

Appropriate Acute Toxicity by Intended Dose Routes: skin sensitization, approximate lethal dose method, limit test, etc.

Other Appropriate Acute Toxicity Studies: oral toxicity by limit test or approximate lethal dose method, skin irritation, etc.

ADME/PK: single or multiple doses.

Genotoxicity: for example, Ames Test, in vitro chromosome aberration test, mammalian cell mutation assay.

28-Day Repeated Dosing Studies in Two Species by Appropriate Routes (One Rodent, One Mammalian Nonrodent): evaluation of injection site or similar considerations might be necessary depending on route of administration.  
notes—

1. In those cases where intended route restrictions (e.g., volume, concentration) preclude an adequate assessment of the toxicity of the excipient, development of a toxicity profile by other relevant routes may be needed.
2. The comparison of toxicity and ADME/PK data between oral and intended routes is critical at this point because that knowledge may set the direction for future toxicity testing (e.g., reproductive toxicity testing conducted by oral route rather than intended route). In addition, relevant studies using the intended route and anticipated duration of exposure may preclude performance of additional studies.

#### Additional Requirements for Specific Exposure Routes

FOR ORAL EXPOSURE: No additional requirements beyond those presented for Baseline Toxicity Data.

FOR MUCOSAL EXPOSURE: No additional requirements beyond those presented for Baseline Toxicity Data.

FOR DERMAL, TOPICAL, OR TRANSDERMAL EXPOSURE:

##### Baseline Toxicity Data—

- Effects of Acute Exposure by Transdermal Dose Route: dermal sensitization study for repeat applications
  - Effects of Repeated Exposures by Transdermal Route
    1. Photoallergy/phototoxicity study
    2. Studies in two species (one rodent, one mammalian nonrodent) by transdermal route.
- Effects of Subchronic Exposure, Reproductive Toxicity Effects—Initial toxicity studies may be performed by the IV route to adequately profile the toxicity of the excipient. This will provide an assessment of potential target organs if an adequate amount of the compound cannot be delivered via a transdermal dosage form. This is dependent upon the results from the ADME/PK studies.

Reproductive studies may also be conducted via oral or IV route with demonstration of absorption (oral) and pharmacokinetic comparisons of the chosen route versus transdermal.

Photocarcinogenicity studies may be required and should be considered if data and the proposed use indicate when evaluating materials to be placed on the skin for prolonged periods of time and exposure to UV light is a factor (e.g., sun block). This also applies to oral, parenteral, and inhalation products where skin drug concentrations exceed plasma drug concentrations for a substantial period of time, or where the candidate material would appear to have the potential for photo-activity or has demonstrated photo-activity.

FOR INJECTABLE DOSAGE FORMS:

##### Background Information—

1. Define compatibility of the dosage form with blood, if appropriate, based on route of exposure.
2. Define the pH and tonicity of injectable dose form, if appropriate, based on the route of exposure.

##### Baseline Toxicity Data—

- Effects of Acute Exposure by Intended Injectable Dose Routes
  1. Include evaluation of injection site irritation in rabbit or dog
  2. Include evaluation of rate of administration.

for inhalation or intranasal exposure:<sup>1</sup>

##### Baseline Toxicity Data—

- Acute Inhalation Toxicity—A limit test that would, for example, use the highest achievable concentration in a 4-hour exposure to vapor, aerosol, or solid particulate. Pulmonary sensitization may be performed along with other appropriate studies. If exposure is to be to an aerosol or solid particulate, particulates of appropriate mass median diameter should be generated.
  - Single and Repeated Dose ADME/PK by Inhalation or Intranasal and Oral Routes
- 28-Day Repeated Dose Inhalation Study in Two Mammalian Species Using Vapor or Particulates of Appropriate Mass Median Diameter: compare to similar oral toxicity data.

for ophthalmic exposure:

Background Information: define pH and osmolarity of topical ocular dose form.

##### Baseline Toxicity Data—

- Effects of Acute Exposure by Ophthalmic Routes: cytotoxicity tests (e.g., agar overlay)
  - Effects of Repeated Exposures by Ophthalmic Routes
    1. Studies in two species (one rodent, one mammalian nonrodent)
    2. Examination of anterior and posterior segments of the eye
    3. Studies on allergenicity potential.

Other Data— Comparison of pharmacokinetic parameters of the route chosen for reproductive studies and the ophthalmic exposure are essential for extrapolation of potential toxicity via the ophthalmic route.

#### DEFINITION OF TERMS

Acute: exposure to a test agent within a single, 24-hour period. Doses may be single, multiple or continuous during a 24-hour period.

Subacute: repeated dosing of a test agent for up to 29 days. Daily doses may be single, multiple or continuous during a 24-hour period.

Subchronic: repeated dosing of a test agent for 30 days to 10% of the lifespan of the test species (90 days in rodents). Daily doses may be single, multiple or continuous during a 24-hour period.

Chronic: repeated dosing of a test agent for more than 10% of the lifespan of the test species (more than 90 days in rodents). Daily doses may be single, multiple or continuous during a 24-hour period.

<sup>1</sup> When designing studies to evaluate use in products intended for use by the inhalation or intranasal route, consideration should be given to the dosing regimen that will be used by humans. The appropriate study protocol for a product intended for inhalation therapy that will result in prolonged exposures (e.g., several hours per day) may differ from that used to evaluate a product that would result in exposure to several metered doses per day.

## 1075 GOOD COMPOUNDING PRACTICES

The purpose of this chapter is to provide compounders with guidance on applying good compounding practices for the preparation of compounded formulations for dispensing and/or administration to humans or animals. This chapter is intended to provide information as a supplement to other relevant chapters. The following discussion is applicable to those engaged in compounding preparations in all pharmacies. It is expected that pharmacists or compounders engaged in the compounding of drugs will compound in conformance with applicable state and federal compounding laws, regulations, or guidelines.

### APPLICABLE DEFINITIONS

Compounding (see [Pharmaceutical Compounding—Nonsterile Preparations](#) (795))—Compounding involves the preparation, mixing, assembling, packaging, and labeling of a drug or device in accordance with a licensed practitioner's prescription of medication order under an initiative based on the practitioner/patient/pharmacist/compounder relationship in the course of professional practice. Compounding includes the following:

- a. Preparation of drugs or devices in anticipation of prescription drug orders based on routine, regularly observed prescribing patterns.
- b. Reconstitution or manipulation of commercial products that may require the addition of one or more ingredients as a result of a licensed practitioner's prescription drug order.
- c. Preparation of drugs or devices for the purposes of, or as an incident to, research, teaching, or chemical analysis.

Categories of Compounding—The categories of compounding are intended to provide an understanding among compounders when different forms of preparations are compounded. It is to be understood that there are levels of training associated with each category. In the categories of compounding described below, certain criteria were used to determine the overall classification.

Category 1 Nonsterile—Simple

Generally, the mixing of two or more commercial products

Category 2 Nonsterile—Complex

Generally, compounding with the bulk drug substances or when calculations are required.

Category 3 Sterile—Risk Level 1

(See Low-Risk Level in USP general chapter (797))

Category 4 Sterile—Risk Level II

(See Medium-Risk Level in USP general chapter (797))

Category 5 Sterile—Risk Level III

(See High-Risk Level in USP general chapter (797))

Category 6 Radiopharmaceuticals

Preparation of radiopharmaceuticals

Category 7 Veterinary

Preparation of veterinary pharmaceuticals

Manufacturing—Manufacturing involves the production, propagation, conversion, or processing of a drug or device, either directly or indirectly, by extraction of the drug from substances of natural origin or by means of chemical or biological synthesis. Manufacturing also includes (1) any packaging or repackaging of the substance(s) or labeling or relabeling of containers for the promotion and marketing of such drugs or devices; (2) any preparation of a drug or device that is given or sold for resale by pharmacies, practitioners, or other persons; (3) the distribution of inordinate amounts of compounded preparations or the copying of commercially available drug products; and (4) the preparation of any quantity of a drug product without a licensed prescriber/patient/licensed pharmacist/compounder relationship.

Component—A component is any ingredient used in the compounding of a drug product, including any that are used in its preparation, but may not appear on the labeling of such a product. (See [Pharmaceutical Compounding—Nonsterile Preparations](#) (795) for additional definitions.)

Compounder—A compounder is a professional authorized by the state to perform compounding pursuant to a prescription order by a licensed prescriber.

### RESPONSIBILITIES OF THE COMPOUNDER

- a. Compounders who are engaged in drug compounding or nutriceutical compounding shall be proficient in compounding and should continually expand their compounding knowledge by participating in seminars and/or studying appropriate literature.
- b. A compounder must be familiar with all of the details of [Pharmaceutical Compounding—Nonsterile Preparations](#) (795), [Pharmaceutical Compounding—Sterile Preparations](#) (797), [Pharmaceutical Calculations in Prescription Compounding](#) (1160), and other applicable state or federal compounding guidelines or laws. In addition, the compounder must be responsible for the following:
  - certifying all prescription orders;
  - approving or rejecting all components, drug product containers, closures, in-process materials, and labeling;
  - preparing and reviewing all compounding records to assure that errors have not occurred in the compounding process;
  - assuring the proper maintenance, cleanliness, and use of all equipment used in a prescription compounding practice;
  - assuring that only authorized personnel shall be in the immediate vicinity of the drug compounding operations;
- c. The compounder must ensure that personnel engaged in compounding wear clean clothing appropriate to the type of compounding performed, e.g., coats, gowns, gloves, masks, shoes, aprons, or other items as needed for protection of personnel from chemical exposures and for prevention of drug contamination.
- d. The compounder must implement procedures to prevent cross-contamination when compounding with drugs (e.g., penicillins) that require special precaution to prevent cross-contamination.

### TRAINING

All personnel involved in the compounding, evaluation, packaging, and dispensing of compounded preparations shall be properly trained for the type of compounding conducted. All training activities will be covered by appropriate standard operating procedures (SOPs) and documentation.

All compounders and all personnel involved in compounding must be well trained and must participate in current, relevant training programs. It is the responsibility of the compounder

Ensure that a training program has been implemented and that it is ongoing. Standards of practice require that all employees be adequately trained in their job functions and that the training is properly documented. Steps in the training procedure will include the following:

- a. All employees involved in pharmaceutical compounding shall read and become familiar with [Pharmaceutical Compounding—Nonsterile Preparations](#) (795), [Pharmaceutical Compounding—Sterile Preparations](#) (797), and [Pharmaceutical Calculations in Prescription Compounding](#) (1160).
- b. All employees shall read and become familiar with each of the procedures related to compounding, including those involving the facility, equipment, personnel, actual compounding, evaluation, packaging, storage, and dispensing.
- c. The compounding shall meet with employees to review their work and answer any questions the employees may have concerning SOPs.
- d. The compounding shall demonstrate the procedures for the employee, and will observe and guide the employee throughout the training process. The employee will then repeat the procedure without any assistance from, but under the direct supervision of, the compounding.
- e. When the employee has demonstrated to the compounding a verbal and functional knowledge of the procedure, then and only then, will the employee be permitted to perform the procedure without direct supervision. However, the compounding should be physically present and should check off the final preparation.
- f. When the compounding is satisfied with the employee's knowledge and proficiency, the compounding will sign off on the documentation records to show that the employee was appropriately trained.
- g. The compounding shall continually monitor the work of the employee and assure that the employee's calculations and work are accurate and adequately performed. The compounding is completely responsible for the finished preparation. The compounding will answer any questions the employee may have concerning the SOPs.

#### PROCEDURES AND DOCUMENTATION

All significant procedures performed in the compounding area will be covered by SOPs and will be documented.

Procedures should be developed for the facility, equipment, personnel, preparation, packaging, and storage of compounded preparations to ensure accountability, accuracy, quality, safety (including access to Material Safety Data Sheets), and uniformity in compounding. Implementing SOPs establishes procedural consistency and also provides a reference for orientation and training of personnel.

Documentation enables a compounding, whenever necessary, to systematically trace, evaluate, and replicate the steps included throughout the preparation process of a compounded preparation.

#### DRUG COMPOUNDING FACILITIES

- a. Compounding facilities shall have an adequate space that is specifically designated for compounding of prescriptions. This area may include a space for the storage of equipment and materials.
- b. Sterile compounded preparations shall be compounded in accordance with the provisions in [Pharmaceutical Compounding—Sterile Preparations](#) (797), and aseptic processes shall be conducted in an area separate and distinct from the area used for the compounding of nonsterile products.
- c. The areas used for compounding shall be maintained in clean, orderly, and sanitary conditions.
- d. The areas for drug compounding shall be maintained in a good state of repair. The plumbing system shall be free of defects that could contribute to contamination of any compounded product. Adequate washing facilities shall be easily accessible to the compounding areas. Such facilities shall include, but not be limited to, hot and cold water, soap or detergent, and an air-drier or single-use towels.
- e. Potable water shall be supplied under continuous positive pressure.
- f. The area for compounding shall have adequate lighting and ventilation.
- g. The area for compounding shall be free of infestation by insects, rodents, and other vermin. Trash shall be held and disposed of in a sanitary and timely manner.
- h. Sewage and other refuse in the area of compounding shall be disposed of in a safe and sanitary manner.
- i. Bulk drugs and other chemicals or materials used in the compounding of drugs must be stored as directed by the manufacturer, or according to USP monograph requirements, in a clean, dry area, under appropriate temperature conditions (controlled room temperature, refrigerator, or freezer). The bulk chemicals shall be stored in a manner such that they are protected from contamination. All containers shall be properly labeled.
- j. If parenteral products are compounded, the compounding shall refer to [Pharmaceutical Compounding—Sterile Preparations](#) (797), and [Injections](#) (1) for compounding technique applications.

#### DRUG COMPOUNDING EQUIPMENT

(See also [Pharmaceutical Compounding—Nonsterile Preparations](#) (795).)

- a. The equipment or utensils used for compounding of a drug preparation shall be of appropriate design and capacity. The equipment should be stored in such a manner as to protect it from contamination, and shall be located in such a place as to facilitate operations for its use, maintenance, and cleaning.
- b. The equipment should be of suitable composition such that the surfaces that contact components are neither reactive, additive, nor absorptive and therefore will not affect or alter the purity of the compounded preparations.
- c. Automated, mechanical, electronic, and other types of equipment used in compounding or testing of compounded preparations should be routinely inspected, calibrated as necessary, and checked to ensure proper performance.
- d. Immediately prior to initiation of compounding operations, the equipment shall be inspected by the compounding to determine its suitability for use.
- e. After use, the equipment should be appropriately cleaned. Extra care should be used when cleaning equipment used in compounding preparations requiring special precaution, e.g., antibiotics, cytotoxins, cancer drugs, and other hazardous materials. If possible, special equipment may be dedicated for such use or if the same equipment is being used for all drug products, appropriate procedures must be in place to allow meticulous cleaning of equipment prior to use with other drugs.

#### COMPONENT SELECTION REQUIREMENTS

- a. The compounding must first attempt to use USP—NF drug substances manufactured in an FDA-registered facility.
- b. The compounding shall also first attempt to use inactive components manufactured in an FDA-registered facility.
- c. If components are not obtainable from an FDA-registered facility or if the FDA and/or the providing company cannot document FDA registration, compounders shall use their professional judgment in first receiving, storing, or using the components that meet official compendial requirements or are provided by another high quality source.
- d. If components of compendial quality are not obtainable, components of high quality such as those that are chemically pure, analytical reagent grade, American Chemical Society-certified, or Food Chemicals Codex grade may be used.
- e. When a component is not obtained from an official compendial source or is not obtainable from the sources mentioned above, the component may be obtained from a source deemed acceptable and reliable in the professional judgment of the compounding.
- f. When a component is derived from ruminant animals (e.g., bovine, caprine, ovine) the supplier shall provide written assurance that these animals were born, raised, and slaughtered in countries where bovine spongiform encephalopathy (BSE) and scrapie are known not to exist.
- g. The compounding shall not use components that are listed by FDA to be withdrawn from the market for public health reasons.
- h. Components shall be stored off the floor, handled and stored to prevent contamination, and rotated so that the oldest stock is used first.

#### PACKAGING AND DRUG PREPARATION CONTAINERS

- a. The compounding shall ensure that the containers and container closures used in packaging the compounded preparations meet the requirements under [Containers—Glass](#) (660), [Containers—Plastics](#) (661) and [Containers—Performance Testing](#) (671). The compounding shall obtain written records from the supplier to show that the containers meet USP requirements.

- b. Containers and container closures intended for compounding of sterile preparations and nonsterile preparations must be handled, sterilized (if appropriate), and stored as described in [Pharmaceutical Compounding—Sterile Preparations](#) (797) and [Pharmaceutical Compounding—Nonsterile Preparations](#) (795). The use of commercially available presterilized containers is encouraged for sterile preparations.
- c. The containers and closures shall be stored off the floor, handled and stored to prevent contamination, and rotated so that the oldest stock is used first.
  - d. The containers and container closures shall be stored in such a way as to permit inspection and cleaning of the work area.
  - e. The containers and container closures shall be made of clean materials that are neither reactive, additive, nor absorptive.
  - f. The containers and closures shall be of suitable material so as not to alter the quality, strength, or purity of the compounded drug.
- g. The compounder shall ensure that the containers and container closures selected to dispense the finished compounded prescription, whether sterile or nonsterile or radiopharmaceutical, meet the criteria in sections (a)–(f) above.

#### COMPOUNDING CONTROLS

- a. The compounder should ensure that there are written procedures for the compounding of drug products to assure that the finished products have the identity, strength, quality, and purity that they purport to have. These procedures should be available in either written form or electronically stored with printable documentation.
- b. The compounder shall establish procedures that include a description of (1) components, their amounts, the order of component additives, and the compounding process; (2) the required equipment and utensils; and (3) the drug product container and closure system.
- c. The written procedures described above shall be followed in execution of the compounding process.
- d. The compounder shall accurately weigh, measure, and subdivide as appropriate.
- e. The compounder shall check and recheck each procedure at each stage of the process to ensure that each weight or measure is correct as stated in the written compounding procedures.
- f. If a component is transferred from the original container to another container (e.g., a powder is taken from the original container, weighed, placed in a container, and stored in that other container), the new container shall be identified with the component name, weight or measure, the lot or control number, the expiration or beyond-use date, and the transfer date.
- g. The compounder should have established written procedures that will describe the tests or examinations to be conducted on the preparation compounded (e.g., the degree of weight variation among capsules) to assure uniformity and integrity of compounded drug preparations.
- h. Appropriate control procedures should be established to monitor the output and to validate the performance of those compounding processes that may be responsible for causing variability in the final compounded preparations. Factors that may cause variability include (1) capsule weight variation; (2) adequacy of mixing to assure uniformity and homogeneity; and (3) clarity, completeness, or pH of solutions.
- i. Appropriate written procedures should be designed to prevent microbiological contamination of compounded drug preparations purporting to be sterile, and these procedures shall be followed. Such procedures shall include validation of sterilization processes (see [Pharmaceutical Compounding—Sterile Preparations](#) (797)).
- j. The compounder should establish appropriate beyond-use dates determined either from available USP–NF monographs, appropriate testing, or from peer-reviewed literature.
- k. The compounder should adopt appropriate storage requirements as provided in Preservation, Packaging, Storage, and Labeling under General Notices and Requirements.

#### LABELING

1. The compounder's preparation label should contain information required by state and federal law and accepted standards of practice. [notes—(a) The compounder shall use the established name or distinct common name (cannot use the trademarked name of a manufactured product). (b) The compounder cannot indicate that the compounded product is therapeutically equivalent to a manufactured product. (c) The label should state that this is a compounded preparation. (d) The compounder shall not use an NDC number assigned to another product.]
  2. The compounder shall label any excess compounded products so as to reference them to the formula used, the assigned control number, and beyond-use date based on the compounder's appropriate testing, published data, or USP–NF standards.
  3. Preparations compounded in anticipation of a prescription prior to receiving a valid prescription should not be prepared in an inordinate amount. A regularly used amount should be prepared on the basis of a history of prescriptions filled by the pharmacy. These preparations should be labeled or documentation referenced with the following:
    - a. A complete list of ingredients or preparation name and reference or established name or distinct common name
    - b. Dosage form
    - c. Strength
    - d. Preparation date
    - e. Name and address of compounder
    - f. Inactive ingredients
    - g. Batch or lot number
    - h. Assigned beyond-use date, based on published data, or appropriate testing, or USP–NF standards.
- Storage conditions for these preparations should be dictated by their composition and sterility, e.g., stored in a clean, dry place under appropriate temperature conditions (controlled room temperature, refrigerator, or freezer.)
4. The compounder should examine the preparation for correct labeling after completion of the compounding process.

#### RECORDS AND REPORTS

- a. The compounder shall maintain records, including but not limited to, the hard copy of the prescription to indicate that the prescription is compounded, and to provide formulation records and compounding records.
- b. The compounder shall keep adequate records of controlled drug substances (scheduled drugs) used in compounding.
- c. All records of all compounded preparations shall be kept for a period of time as set forth in the federal and state laws or regulations. Such records shall be readily available for authorized inspection.
- d. The compounding records shall include the manufacturer and lot number of all ingredients.

#### COMPOUNDING FOR A PRESCRIBER'S OFFICE USE

- a. Compounds may prepare compounded drug preparations for a prescriber's office use only where permitted by federal and state requirements.
- b. An order by the prescriber indicating the formula and quantity ordered may be filed in the compounder's facility.
- c. Where compounding for office use is permitted, the compounder shall compound the preparation for the sole purpose of administration by or for the prescriber.
  - d. A record of the compounding process shall be maintained.
  - e. A label must be generated and a number may be assigned.

#### COMPOUNDING VETERINARIAN PRODUCTS

- a. Compounds shall compound prescriptions for animals on the basis of prescription orders.
- b. These prescriptions shall be handled and filled according to the guideline available for compounding of veterinarian products.

Topic/Question	Contact	Expert Committee
----------------	---------	------------------

## BACKGROUND

Many of the principles in this general information chapter are derived from an international guidance on the extent and point of application of appropriate good manufacturing practice principles. It is intended to assist excipient manufacturers in determining whether the methods used in, and the facilities and manufacturing controls used for, production adequately ensure that an excipient possesses the quality, purity, safety, and suitability for use that it purports to possess.

The principles and information in this chapter can be applied to the manufacture of all bulk pharmaceutical excipients (referred to throughout this document as "excipient(s)") intended for use in human drugs, veterinary drugs, and biologics. It covers the quality systems and the extent of good manufacturing practices necessary throughout the chain of production up to and including delivery to customers. As an international guidance document, it does not provide information for all national legal requirements nor cover in detail the particular characteristics of every excipient. The quality system standard used as a framework for this chapter is ISO 9002, which is appropriate to manufacturing. Information specific to excipients has been added. Because of the diversity of excipients, some principles in this information chapter may not be applicable to certain products and processes.

This information chapter combines existing governmental regulatory good manufacturing practices principles and international quality management system requirements as developed by The International Organization for Standardization (ISO). In view of the increasing globalization of the pharmaceutical industry and the harmonization of pharmaceutical registration requirements, deference to both schemes is becoming necessary. Therefore, relevant portions of both manufacturing concepts are employed throughout this chapter.

The General Guidance section provides an overview of the appropriate manufacturing practices criteria applicable to excipient manufacture and the point of application of excipient good manufacturing practices and quality systems. This section also recommends measures to limit contamination of an excipient and provides the relationship of excipients to finished dosage forms. For a list of terms and their definitions used in this information chapter, see [Appendix 1](#). The section Excipient Quality Systems provides information on the requirements necessary for compliance with relevant good manufacturing practice principles and implementation of an excipient quality system. Information for production facility requirements are included under Process Control. No attempt has been made to include details specific to particular excipients. The information under [Appendix 2](#), General Auditing Considerations, sets forth key criteria to aid in the audit of an excipient manufacturing facility.

## GENERAL GUIDANCE

International regulations governing drugs require that components of the drugs be manufactured, processed, packed, and held in accordance with good manufacturing practices. Unlike other pharmaceutical products and components, until now there was no guidance that specifically addressed the manufacture of bulk pharmaceutical excipients.

Excipients are substances, other than the active drug substance or finished dosage form, that have been appropriately evaluated for safety and are included in drug delivery systems 1) to aid in the processing of the drug delivery system during its manufacture; 2) to protect, support, or enhance stability, bioavailability, or patient acceptability; 3) to assist in product identification; or 4) to enhance any other attribute of the overall safety, effectiveness, or delivery of the drug during storage or use.

The application of good manufacturing practices to excipients is relevant when it is determined that a chemical is intended for use as a component of a drug product. Excipient manufacture should be carried out in accordance with the manufacturing practice concepts consistent with the information in this chapter. The objective of excipient good manufacturing practices is to ensure that excipients are manufactured with the appropriate quality characteristics.

Excipients generally are manufactured on a large scale, which means that the use of automated process controls and continuous stream processing are more likely to be utilized. Production equipment and operations will vary depending on the type of excipient being produced, the scale of production, and the type of operation (e.g., lot or batch versus continuous). The use of automated equipment is appropriate when adequate inspection is conducted and calibration and maintenance procedures are followed.

Manufacturing practice requirements increase as the process progresses. At some logical processing step, usually well before the final finishing operation, appropriate manufacturing practices should be imposed and maintained throughout the remainder of the process. To determine the processing step at which these manufacturing practices should be implemented, good judgment and a thorough knowledge of the process are required. A detailed process flow should identify the unit operations, equipment used, stages at which various substances are added, key steps in the process, critical parameters (time, temperature, pressure, etc.), and monitoring points.

ISO 9000 series is a quality system standard of general application that can be applied to cover every aspect of manufacturing to the benefit of both the manufacturer and customer. It has taken several years since its introduction in 1987 for the ISO 9000 series to be utilized worldwide. There is no current regulatory requirement in Europe, Japan, or the United States for third party certification. A manufacturer may apply the standard with or without certification. However, certification has the benefit of providing assurance to customers that conformance to this quality system has been independently confirmed. Incorporation of GMP requirements into the ISO 9000 quality system enhances not only the quality system, but a company's operational procedures as well. Final dosage formulators worldwide increasingly regard compliance with ISO 9002 as an essential qualification for their suppliers.

Obtaining certification is a business decision and is not discussed in this general information chapter.

## Excipient Purity

The processes used for the production of bulk pharmaceutical excipients and those used for the production of bulk pharmaceutical chemicals are similar. Both can be manufactured by chemical synthesis, recombinant DNA technology, fermentation, enzymatic reactions, recovery from natural materials, or any combination of these processes. Impurities, contaminants, carriers, vehicles, inert ingredients, diluents, or unwanted crystalline or molecular forms may be present in the raw materials. Therefore, the starting materials for excipients may not be required to be manufactured in accordance with the manufacturing practices specified in this chapter because often the starting materials (or their derivatives) undergo significant chemical change and physical modification or blending, with the result that many of the impurities present in the starting materials are removed. The ultimate manufacturing objective is purification and physical or chemical alteration, which is accomplished by various chemical, physical, or biological processing steps. The effectiveness of these steps is confirmed by chemical, biological, and physical testing of the excipient. Excipients, once synthesized or isolated, normally undergo additional, extensive purification during manufacture.

Many excipients have applications other than for pharmaceutical uses and are used in food, cosmetics, or industrial products. Thus, environmental conditions, equipment, and operational techniques employed in excipient manufacture often reflect the chemical industry rather than the pharmaceutical industry. Many chemical processes have the potential to produce toxic impurities from side reactions. Therefore, careful process control may be essential. Also, the manufacturing environments may contain deleterious substances. However, chemical processes used to manufacture excipients are either performed in closed systems that afford protection against such contamination—even when the reaction vessels are not enclosed in buildings—or else these processes are in environments that must be controlled.

It is important that manufacturers identify and set appropriate limits for impurities. These limits should be based upon appropriate toxicological data, or limits described in national compendia as requirements, as well as sound manufacturing practice considerations. Manufacturing processes should be adequately controlled so that the impurities do not exceed such established specifications.

## Excipients in Finished Dosage Forms

The formulator of finished dosage forms is highly dependent on the excipient manufacturer to provide bulk pharmaceutical excipients that are uniform in chemical and physical characteristics. This is particularly important in the context of the product approval process where bioequivalency comparisons are made between pivotal clinical biobatch production and commercial scale-up lots or batches. To provide adequate assurance of drug product performance, the excipient used to manufacture commercial lots or batches should not significantly differ from those used in biobatches. Where significant differences do occur, additional testing by the manufacturer of finished dosage forms may be required to establish the bioequivalence of the finished product. It remains equally important to ensure that the bioequivalence of subsequent, post-approval commercial lots or batches of drug product is

not adversely affected over time.

In general, excipients are used as purchased. Consequently, impurities present in the excipient will be present in the finished dosage form. While manufacturers of dosage forms may have limited control over excipient quality through specifications, the excipient manufacturer has greater control over physical characteristics, quality, and the presence of impurities in the excipient.

Excipients are used in different types of dosage forms where physical characteristics, such as particle size, may be important. While it is primarily the responsibility of the manufacturer of finished dosage forms to identify the particular physical characteristics needed, it is the responsibility of the excipient manufacturer to adequately control processes to ensure the excipient's consistent conformance to specifications. The excipient's end use should be identified and considered during inspection of excipient manufacturers' facilities.

Particularly important is whether the excipient is a direct component of a drug dosage form, whether the excipient will be used in the preparation of a sterile dosage form, or whether the excipient is represented as pyrogen free. The excipient manufacturer is responsible for ensuring that excipients are pyrogen free if the manufacturer makes such a representation in specifications, labeling, contractual agreement, or a Drug Master File (DMF).

#### EXCIPIENT QUALITY SYSTEMS

The information described below can be used as the basis for a quality system in the manufacture of excipients. Procedures that are utilized in the manufacture and control of excipients should be written. Conformance to those procedures should be documented. A quality manual is a documented base and is intended to describe the quality policy and the commitment of the supplier to quality. The procedural system should have adequate formal controls related to procedure approval, revision, and distribution. These controls should provide assurance that the proper version of a procedure is being utilized throughout the operation.

##### Management and Employee Responsibility

**Quality Policy**— Management should demonstrate commitment to a quality policy that should be implemented within the operational unit. Management should participate in the development of the company's quality policy and provide the resources necessary for development, maintenance, and review of such policy and quality system at least annually. Management should be committed to this policy and should appoint appropriate company personnel to be responsible for coordination and implementation of the quality system.

**Organization**— There should be a quality unit, independent of production, that has the responsibility and authority to approve or reject all components, in-process materials, packaging materials, and finished excipients. The quality unit should have the authority to review production records to ensure that no errors have occurred or, if errors have occurred, that they have been fully investigated. The quality unit should be responsible for approving or rejecting excipients manufactured, processed, packaged, or held under contract by another company. The quality unit can delegate these responsibilities if proper controls, such as periodic audits and documentation of training, are in place. Adequate laboratory facilities for the testing and approval or rejection of raw materials, packaging materials, in-process materials, and finished excipients should be available to the quality control unit.

It is the responsibility of an independent unit, usually the quality assurance group, which is independent of production, to participate in issuing procedures, authorizing changes to processes, specifications, procedures, and test methods and in investigating failure and complaints.

An organization chart by function should be available showing interdepartmental relationships as well as relationships to the management of the company. As a minimum, all quality assurance, quality control, production maintenance, and engineering functions should have clear job descriptions.

##### Personnel—

**Employee Responsibility**— Employees engaged in the manufacture, processing, packaging, or holding of an excipient should wear clean clothing appropriate for the duties they perform. Protective apparel, such as head, face, hand, and arm coverings, should be worn as necessary to protect excipients from contamination. Only employees authorized by supervisory personnel should enter those areas of the buildings and facilities designated as limited-access areas.

Employees should practice good sanitation and health habits. Any person shown at any time (either by medical examination or supervisory observation) to have an apparent illness or open lesions that may adversely affect the safety or quality of excipients should be excluded from direct contact with components, excipient containers and closures, in-process materials, and finished excipients until the condition is corrected or determined by competent medical personnel not to jeopardize the safety or quality of the excipients. All employees should be instructed to report to supervisory personnel any health conditions that may have an adverse effect on excipients.

**Other Requirements**— There should be an adequate number of qualified personnel to perform and supervise the manufacture, processing, packaging, or holding of each excipient in a manner consistent with the information in this guide. Management should establish adequate and continued good manufacturing practices and personal hygiene training for all employees handling products so that they understand the precautions necessary to prevent the contamination of excipients.

**Consultants**— Consultants advising on the manufacture, processing, packaging, or holding of excipients should have sufficient education, training, and experience, or any combination thereof, to advise on the subject for which they are retained. Records should be maintained listing the name, address, and qualifications of any consultants and the type of service they provide.

**Technical Assistance**— The excipient manufacturer should establish and maintain procedures for providing such technical assistance as may be required.

##### Manufacturer and User Responsibilities

**Contract Review**— The manufacturer and user should mutually agree upon the excipient specifications. The manufacturer must have the facility and process capability to consistently meet the mutually agreed upon specifications of the excipient(s). Subcontracting or significant changes to a supplier's audited process that could affect the physical, chemical, or functionality of the excipient in a final dosage form should be immediately communicated or pre-approved as mutually agreed upon between customer and supplier.

**Document and Data Control**— The excipient manufacturer should have a system to control all documents and data that relate to the requirements of the quality system. When these documents were issued and where they are located should be recorded. To identify the most recent document, each document should include a unique identifier, date of issue, and revision number on each page. The issuing department also should be identified. All changes, where practical, and the reasons for the change should be documented. Documents and subsequent changes to the documents should be reviewed and approved by designated qualified personnel before issuance to the appropriate areas identified in the documents.

**Purchasing**— The purchaser should verify that the supplier of raw materials, components, and services for the manufacture of excipients has the capability to consistently meet the agreed-upon requirements. This may include periodic audits of the vendor's plant, if deemed necessary. Purchasing agreements should contain data clearly describing the product ordered, including where applicable, the following:

- The name, type, class, style, grade, item code number, or other precise identification traceable to the raw material specification.
- Drawings, process requirements, inspection instructions, and other relevant technical data, including requirements for approval or qualification of product, procedures, process equipment, and personnel.

These requirements also apply to selection and control of subcontractors. Subcontractors include toll manufacturers and contract laboratories.

**Control of Customer Supplied Products**— The manufacturer should establish and maintain procedures for verification, storage, and maintenance of customer supplied products intended for incorporation into the customer's excipients. Verification by the manufacturer does not relieve the customer of the responsibility to provide an acceptable product. Any product that is lost, damaged, or is otherwise unsuitable for use should be recorded and reported to the customer. In this case, procedures should be in place for acceptable disposition and replacement of the product.

**Product Identification and Traceability**— All items, from the received raw materials, through the in-process goods, to the finished products, should be clearly identified and traceable through a documented system. The system should allow the traceability of product upstream and downstream. Identification of raw materials used in the production of processed materials should be traceable using a batch numbering system or any other appropriate system. The finished product should be traceable to the customer and retrievable in case of the need for a product recall.

**Labeling**— Labeling requirements for excipient packages are subject to applicable national and international regulatory requirements, which may include transportation and safety measures. Procedures should be employed to protect the quality and purity of the excipient when it is packaged, and to ensure that the correct label is applied to all containers. A good system of labeling should have, at a minimum, the following features: the name of product; the manufacturer and distributor; a lot or batch number from which the complete lot or batch

...story can be determined; a file of master labels [note—A designated individual should review incoming labels or labels printed on demand against the appropriate master labels], storage of labels in separate containers or compartments to prevent mix-ups; formal issuance of labels by requisition or other document; issuance of an exact number of labels, sufficient for the number of containers to be labeled, retention copies, and calculated excesses, if any; reconciliation of the number of labels issued with the number of unit packages and retention labels, together with the destruction of excess labels bearing lot or batch numbers; and avoidance of labeling more than one lot or batch at a time without adequate separation and controls.

In instances where excipients are labeled on the packaging line, packaged in pre-printed bags, or bulk shipped in tank cars, there should be documentation of the system used to satisfy the intent of the above requirements.

If the need for special storage conditions exists (e.g., protection from light, heat, etc.), such restrictions should be placed on the labeling.

**Retained Samples**— Reserve samples of an excipient should be retained for one year after the expiration or re-evaluation date, or for one year after distribution is complete, whichever is longer. Sample size should be twice the amount required to perform specification testing.

#### Process Control

**Buildings and Facilities**— Any building or buildings used in the manufacture, processing, packaging, or holding of an excipient should be of suitable size, construction, and location to facilitate cleaning, maintenance, and proper operations.

**Cross-contamination Prevention**— Cross-contamination should be a consideration in the design of the manufacturing process and facility. The minimization of the degree of cross-contamination should be dependent on the safety and intended use of the excipient.

It is expected that the degree of precautions taken in minimizing cross-contamination be appropriate to the conditions of the manufacturing facility. Where two different grades of the same excipient are manufactured in the same building or the same equipment, a trace carryover from the production of the previously produced grade to the present production may occur. This can be considered acceptable if shown that the extent of commingling does not change the functionality and safety of the excipient.

When the excipient product is initially recovered, it should be in a clean environment and not exposed to airborne contaminants such as dust, other excipients, or industrial chemicals. The primary consideration is that the building and facilities be designed so that operations performed within do not contribute to an actual or potential contamination of the excipient.

**Air Handling**— Excipient plant air handling systems should be designed to prevent cross-contamination. For dedicated areas processing the same excipient, it is permissible to recycle a portion of the exhaust air back into the same area. The adequacy of such a system of operation for multi-use areas, especially if several products are processed simultaneously, should be carefully analyzed.

In multi-use areas where several products are completely confined in closed vessels and piping systems, the extent of filtration of the supply air (combined fresh make-up air and recycled air) is acceptable if the conditions are consistent with other existing regulations (e.g., environmental, safety). However, there should be data to demonstrate adequacy of the air handling system. Where for process reasons an inert gas is needed, these same rules should apply.

**Cleaning and Sanitary Conditions**— Adequate cleanliness is an important consideration in the design of excipient manufacturing facilities. Any building used in the manufacture, processing, packaging, or holding of an excipient should be maintained in an appropriately clean and sanitary condition. There should be written procedures assigning responsibility for sanitation and describing in sufficient detail the cleaning schedules, methods, equipment, and materials used in cleaning the buildings and facilities; such written procedures should be followed and periodically reviewed. Conformance should be documented.

All buildings should be free of infestation by rodents, birds, insects, and other vermin. Waste should be held and disposed of in a timely and appropriate manner. However, many starting materials, particularly botanicals, may have some unavoidable contamination, such as rodent or other animal filth or infestation. The manufacturer should have sufficient control methods to prevent the increase of such contamination or infestation in holding areas or its spread to other areas of the plant.

**Other Facility Concerns**— Any building used in the manufacture, processing, packaging, or holding of an excipient should be maintained in a good state of repair. The following items are of particular concern:

**LIGHTING**— Adequate light should be provided in all areas.

**PLUMBING**— Water that comes in contact with an excipient should be supplied under continuous positive pressure in a plumbing system free of defects that could contribute contamination to the excipient. Drains should be of adequate size and, where connected directly to a sewer, should be provided with an air break, or other mechanical device, to prevent back-siphoning.

**WASHING AND TOILET FACILITIES**— Adequate washing facilities should be provided, including hot and cold water, soap or detergent, air dryers or single service towels, and clean toilet facilities easily accessible to working areas.

**Equipment**— Equipment used in the manufacture, processing, packaging, or holding of an excipient should be of appropriate design, adequate size, and in a suitable location to facilitate its operation, cleaning, and maintenance.

**Outside Equipment**— Some fermentation tanks, reaction vessels, and certain other equipment may not be situated within a building, and a considerable amount of processing may occur out-of-doors. Such processing is acceptable provided it occurs in a closed system.

**Multipurpose Equipment**— Many excipients are produced using multipurpose equipment. With few exceptions, such multiple usage is satisfactory provided the equipment can be adequately cleaned according to validated written procedures. The program should take into consideration the need for different cleaning procedures, depending on the safety considerations of the product or intermediate and what product or intermediate was previously produced. Products that leave residues that cannot be easily removed should be produced in dedicated equipment.

Where multipurpose equipment is in use, it is important to be able to determine previous usage when investigating cross-contamination or the possibility of such contamination. An equipment cleaning and use log, while desirable and perhaps preferable, is not the only method of determining prior use. Any documentation system that clearly identifies the previous lot or batch and shows that the equipment was cleaned is acceptable.

Cleaning and disinfection procedures should be properly established by competent personnel using the model product approach, when applicable. These procedures should be designed to meet or exceed the particular needs of the product and process involved and be set down in a written schedule available for the guidance of employees and management. An effective and regular cleaning program should be put in place to remove product residues and dirt, which may also contain microorganisms and act as a source of contamination.

The supplier should demonstrate the effectiveness and efficiency of the cleaning and disinfection procedures for each piece of equipment, and the cleaning status of equipment should be recorded. Validation data should prove that the cleaning procedure is acceptable. An evaluation should consider the potential impact that traces of contaminant may have on the product supplied to the customer. All equipment that has been in contact with contaminated material should be thoroughly cleaned and disinfected before coming in contact with an excipient.

**Controlled Environment**— A controlled environment may be necessary to avoid microbial contamination or degradation caused by exposure to heat, air, or light. The degree of protection required may vary depending on the stage of the process. Equipment should be designed to minimize the possibility of contamination caused by direct operator contact in such activities as the unloading of centrifuge bags, use of transfer hoses (particularly those used to transfer powders), and the operation of drying equipment and pumps. The sanitary design of transfer and processing equipment should be evaluated. Those with moving parts should be assessed in regard to the integrity of seals and packing materials to avoid their contaminating the product.

Special environments required by some processes should be monitored at all times to ensure product quality (e.g., inert atmosphere, protection from light). Where inert atmosphere is required, the gas should be treated as a raw material. If interruptions in a special environment occur, adequate evidence and appropriate rationales should be documented to show that such interruptions have not compromised the quality of the excipient. Such environmental concerns become increasingly important after purification of the excipient has been completed.

**Construction**— Process equipment should be constructed so that their contact surfaces will not be reactive, additive, or absorptive so as to alter the quality attributes of the excipient. Substances required for operation, such as lubricants or coolants, should not come into contact with components, excipient containers, closures, in-process materials, or finished

excipients. Materials acceptable for food grade use should be used where product exposure or contamination is possible.

Maintenance— Equipment and utensils should be maintained and sanitized (where necessary) at appropriate intervals to prevent malfunctions or contamination that would alter the standards and characteristics of the excipient beyond the official, or otherwise established, requirements. Written procedures should be established and followed for maintenance of critical equipment, including utensils, used in the manufacture, processing, packaging, or holding of the excipient. Records should be kept of preventive maintenance of equipment and utensils, a description of the maintenance performed, and the batch or lot number of the excipient that was present in the equipment before and after the activity.

These records can be in the form of a log, computer database, or other appropriate documentation, provided the system can properly identify who was responsible for performing each function.

Water Systems and Water Quality— Potable water may be used in the production of excipients, provided that established water quality standards are consistent with regulatory requirements for source drinking water. If the manufacturer specifies water of pharmacopeial quality in the specifications or DMF, the water should meet the particular pharmacopeial standards. Data from periodic testing should be available to show compliance with chemical and microbiological standards, including freedom from pathogenic organisms. Data need not be generated by the manufacturer if such data are available from municipal water authorities.

While drinking water is used for many excipient processes, Purified Water is also widely used in the manufacture of excipients. Because of the well-recognized potential for microbial growth in deionizers and ultrafiltration or reverse osmosis systems used to produce Purified Water, such systems should be properly validated and controlled.

Proper control methods include the establishment of water quality specifications and corresponding action levels, remedial action when microbial levels are exceeded, and adequate maintenance procedures such as regeneration and sanitation or sterilization.

Appropriate specifications for chemical and microbial quality should be established and periodic testing conducted. Such specifications will vary depending on the process and the point in the process when the water is used. The water quality standards should reflect the intended use of the excipient. The frequency of microbial and chemical testing of Purified Water is dependent upon a variety of factors, including the test results and the point in the process (e.g., final wash in centrifuge) at which such water is used.

Similar principles to those discussed above for Purified Water apply to Water For Injection used in sterile and pyrogen-free excipient processing. The water for injection (WFI) system should be monitored for microorganisms, and the validation data and reports of monitoring should be reviewed as is required for finished dosage forms.

Most purified and WFI water systems, including ultrafiltration and reverse osmosis systems, have the potential for the development of endotoxins. If the final excipient product purports to be pyrogen free or sterile, or will be used in preparing parenteral products, validation of the system to control endotoxins should be conducted and routine testing of the process water for endotoxins should be performed (preferably by the LAL method).

Aseptic and Sterile Manufacturing— The manufacture of sterile excipients for use in aseptic or sterile processing presents technical challenges. Because humans are the primary source of contamination in an aseptic operation, the process should be designed to eliminate this direct contact. Those aseptic excipient operations that utilize considerable operator involvement should have adequate controls.

The excipient manufacturer should document the sanitizing of critical processing equipment. Processes used for the sterilization of equipment should be validated. The manufacturer also should verify that no chemical interaction with the product occurs.

There are guidelines and compliance programs that provide detailed guidance for the manufacture of sterile products. These documents should be reviewed in association with sterile excipient manufacturing inspections.

Validation of Process and Control Procedures— Excipient manufacturers are expected to adequately determine and document that all significant processing steps are performed consistently. The type of excipient, the breadth of the specification relative to the degree of process control, and other factors determine the extent of the process development and documentation required.

An important factor in the assurance of product quality includes the adequate design and control of the manufacturing process because product testing alone is not sufficient to reveal variations that may have occurred. Each step of the manufacturing process should be controlled, to the extent necessary, to ensure that the excipient meets established specifications. The concept of process validation is a key element in assuring that these quality assurance goals are met. Documentation describing the process reactions, operating parameters, purifications, impurities, and key tests needed for process control should be written, thus providing the basis for validation.

Many manufacturers already possess the data necessary to validate that their processes perform in a consistent manner. For example, limitations of a reaction or purification step are usually identified in the development phase. Known impurities and tests used to determine their levels are also established at this phase. Thus, when the process is scaled up to production of a lot or batch size, a comparison can be made with development lots or batches. Scale-up and development reports, along with purity profiles, would constitute an appropriate validation report.

Stability— While many excipient products are very stable and may not require extensive testing to ensure stability, the stability of excipients is an important contributing factor to the stability of the finished dosage form. The stability of excipients may be affected by undetected changes in raw material specifications or subtle changes in manufacturing procedures. Excipient products also may be shipped in a large variety of different packaging types that can affect their stability (e.g., drums that are metal and plastic, bags and bottles that are plastic or glass, tank cars, etc.).

Some excipients may be available in different grades (i.e., various molecular weights of a polymer or different monomer ratios, etc.) or some may be mixtures or blends of other excipients. These excipients may be very similar to others within a product group. Minor quantitative differences of some of the components may be the only significant variation from one product to another. For these types of excipients, a model product approach may be appropriate to assess the stability of similar excipients. Stability studies would involve the selection of several model products that would be expected to simulate the stability of the product group being assessed. This election should be based on scientifically sound theories.

Data from stability studies of these model products can be used to determine theoretical stability for similar products.

There should be a documented testing program designed to assess the stability characteristics of excipients. The results of such stability testing should be used in determining appropriate storage conditions and their re-evaluation or expiration dates. The testing program should be ongoing and should include the following: the number of lots per year, sample size, and test intervals; the storage conditions for samples retained for testing; those test methods that are necessary to indicate stability; and a simulation of containers and storage time equivalent to those conditions in the marketplace, if possible.

For excipients that have been in the market for a long time, historical data may be used to assign the shelf life and storage conditions. The testing program can also be modified based on available historical data.

Expiration Dating and Re-evaluation— If testing indicates a short shelf life under anticipated storage conditions, the excipient should either be labeled with an expiration date or be re-evaluated at appropriate intervals to determine its continued suitability for use. If the excipient has been in the market for a long time, the expiration date or its re-evaluation must be derived from appropriate stability testing or from historical data. With few exceptions, expiration dates are not presently considered to be a general requirement for all excipients. Thus, the absence of an expiration date is not objectionable.

Process Changes (Change Control)— The excipient manufacturer should establish and maintain written procedures for the identification, documentation, appropriate review, and approval of changes within the production processes. An independent group (such as regulatory affairs, quality assurance, etc.) should have the responsibility and authority for the management and final approval of changes. Significant operational changes should be based on validated excipient studies. The effect of the changes should be communicated to both internal and external customers.

Lot or Batch Production Records— There is increased use of computer systems to initiate, monitor, adjust, and otherwise control manufacturing processes. These operations may be accompanied by recording charts that show key parameters (e.g., temperature) at suitable intervals, or even continuously throughout the process. In other cases, key measurements (e.g., pH) may be momentarily displayed on a monitor screen but not available in hard copy. In both cases, conventional hard-copy lot or batch production records such as those showing the addition of ingredients, actual performance of operations by identifiable individuals, and other information usually seen in conventional records may not be generated.

Therefore, documentation of the excipient manufacturing process should include a written description of the process and production records.

As a practical matter, when computers and other sophisticated equipment are employed, the following considerations are essential: systems and procedures that show the equipment

and software is in fact performing as intended; checking and calibrating the equipment at appropriate intervals; retention of suitable backup systems, such as copies of the program and files; and assurance that changes in the program are documented, validated, and made only by authorized personnel.

In-Process Blending or Mixing— In-process blending or mixing to ensure batch uniformity or to facilitate processing is acceptable provided it is adequately controlled and documented.

In order to ensure batch uniformity, homogeneous mixing of all materials, to the extent feasible, and reproducibility from batch to batch is essential. Blending of batches or lots that individually do not conform to specifications with other lots that do conform (to salvage or hide adulterated material) is not an acceptable practice.

In-process blending or mixing, which is performed to facilitate processing, includes the use of holding tanks, reprocessing, and repeated crystallizations. Incidental carryover is another type of in-process mixing that frequently occurs and is usually acceptable because cleanup between successive lots or batches of the same excipient is not normally required to maintain quality levels during a production operation.

Solvents, Mother Liquors, and Second Crops— Many excipients are extracted from, or purified by, the use of organic solvents. These solvents are normally removed by drying the moist excipient. It is important that excipient specifications include tests and limits for residues of solvents.

Solvents may be recovered and reused in the same process or different processes provided that the recovered solvents are shown to meet appropriate standards prior to reuse or commingling with other approved material. Mother liquors or filtrates containing recoverable amounts of excipients, reactants, or intermediates are frequently reused. Recovery procedures for such excipients are acceptable if the recovered excipient meets its specifications and recovery procedures are indicated in lot or batch production records. Recovery procedures for reactants and intermediates are acceptable if the recovered materials meet suitable specifications.

#### Inspection and Testing

Testing programs should include the establishment of scientifically sound and appropriate specifications, standards, sampling plans, and test procedures designed to ensure that components, containers, closures, in-process materials, labeling, and finished excipients conform to established standards.

It is not appropriate to retest a sample, which previously gave a nonconforming test result, and to release the material based solely on the retest results. This would only be appropriate if it is demonstrated that the original test result was erroneous based on a documented investigation. Otherwise, statistical treatment of all the test data, including both the original and retest, should be used to justify release of the lot. These same principles apply when the representative of the sample is suspect. The excipient manufacturer should establish procedures for identifying adequate statistical techniques that may be required for verifying the acceptability of process capability and product characteristics.

Test Status— There should be a system to identify the inspection status of all materials including raw materials, intermediates, and finished products. While storing materials in properly identified locations is preferred, any means which clearly identifies the test status is satisfactory.

Upon receipt, raw materials should be placed in quarantine status and should not be used prior to acceptance. Effective quarantine can be established with suitable identifying labels or signs, or validated documentation systems. With increasing frequency, quarantine and documentation is widely accomplished with a computer system in lieu of a physical stock control system. This is acceptable provided that system controls are adequate to prevent use of unreleased material.

Raw Material Testing— Raw materials should be tested or otherwise verified prior to use. Verification should include a supplier certificate of analysis and, wherever feasible, at least an identification test. There should be clear guidelines established for the approval of each raw material.

Raw material specifications should be written documents, even if only minimal requirements are specified. Such specifications will vary in depth and sophistication, depending on various factors such as the critical nature of the raw material, its function in the process, the stage of manufacture, and the hazards associated with sampling. The specifications should be organized to separate those tests that are routine from those that are performed infrequently or only for new suppliers.

Raw materials are usually subjected to an identity test and additional testing to determine if they meet appropriate specifications. Laboratory controls should include a comprehensive set of meaningful analytical procedures designed to substantiate that the raw materials meet established specifications. Some raw materials may not be acceptance tested by the manufacturer because of the hazards involved. This is acceptable where there is a reason based on safety or other valid considerations. In such a circumstance, assay certification for each lot from the vendor should be on file. There should always be some evidence of an attempt by the excipient manufacturer to establish identity, even if it is only a visual examination of containers, examination of labels, and recording of the lot or batch numbers from the labels.

In-Process Testing— Excipients are normally subject to various in-process tests to show that a manufacturing process is proceeding satisfactorily. Such tests often are performed by production personnel in production laboratory facilities. Approval to continue with the process is often issued within the production department. The important considerations are that specified tests are performed by trained personnel and recorded, and that results are within specified limits.

In-process inspection and testing should be performed based upon monitoring the process or actual sample analysis at defined locations and times. The results should conform to established process parameters or acceptable tolerances. Work instructions should delineate the procedure to follow and how to utilize the inspection and test data to control the process.

Finished Product Testing and Release— Finished product testing should be performed by the quality unit and should conform to written specification. There should be a procedure that ensures that appropriate manufacturing documentation, in addition to the test data, is evaluated prior to release.

All appropriate records relating to inspection and testing should be available for review. Where the process is continuously monitored, acknowledgment that the process was monitored and the results of the monitoring should be available.

Control of Nonconforming Product— Any raw material, intermediate, or finished excipient found not to meet specifications should be clearly identified and segregated to prevent inadvertent use or release for sale. A record of nonconforming product should be maintained. All incidence of nonconformance should be investigated to identify the root cause. This investigation should be documented and corrections made to prevent recurrence of the problem.

Procedures should exist for the evaluation and fate of nonconforming products. Nonconforming product should be reviewed in accordance with documented procedures to determine its final outcome. The nonconforming product may be reprocessed or reworked to meet the specified requirements and then accepted with agreement by the customer, regraded for alternative applications, or destroyed.

Returned Excipient Products— Returned excipient products should be identified as such and held. If the conditions under which the products have been held, stored, or shipped before and during return, or if the condition of the container casts doubt about its safety, identity, strength, quality, or purity, the product should be destroyed unless examination, testing, or other investigations prove that the excipients meet appropriate standards of safety, quality, or purity.

Records of returned products should include the name and lot number (or control batch number), reason for the return, quantity returned, date of disposition, and ultimate fate of these products. Procedures for the holding, testing, and reprocessing should be written and followed.

Corrective and Preventive Actions— The supplier should establish, document, and maintain procedures for

- investigating the cause of nonconforming product, returns, and complaints along with the corrective action needed to prevent recurrence;
- analyzing all processes, work operations, concessions, quality records, and service reports to detect and eliminate potential causes of nonconforming product;
  - initiating preventive actions to deal with problems to a level corresponding to the risks encountered;
  - applying controls to ensure that corrective actions are taken and that they are effective; and
  - implementing and recording changes in procedures resulting from corrective action.

Reprocessing or Reworking— Reprocessed or reworked product should be re-inspected in accordance with documented procedures. Reprocessing or reworking of an excipient may be acceptable. However, merely relying on final testing of the reprocessed excipient as a means of demonstrating compliance to specification and neglecting the investigation and evaluation of the manufacturing process is unacceptable.

Reprocessed material should also be evaluated and documented to ensure that the lot or batch will conform with all established standards, specifications, and characteristics equivalent to those of the original material. There should be a sufficient investigation, evaluation, and documentation to show that the reprocessed excipient is at least equivalent to other acceptable products and that the nonconformance did not result from an inadequate process. If the need for reprocessing resulted from human error, it may indicate other deficiencies, such as inadequate training or work instructions.

processing or rework that is not a normal part of the validated process should not be performed without the review and approval of an independent group such as regulatory affairs or quality assurance, etc.

#### Inspection, Measuring, and Test Equipment

Calibration of all in-process instruments identified as quality instruments, as well as test equipment used in the laboratory, should be traceable to recognized standards. Laboratory instruments, such as spectrometers, viscosimeters, and other apparatus, as well as reagents, buffer solutions, and standard solutions would be included.

The control program should include the standardization or calibration of reagents, instruments, apparatus, gauges, and recording devices at suitable intervals in accordance with an established written program containing specific directions, schedules, limits for accuracy and precision, and provisions for remedial action in the event accuracy or precision limits are not met. Reagents, instruments, apparatus, gauges, and recording devices not meeting established specifications should not be used.

Computer systems used to verify that the product conforms to specifications should be audited to ensure satisfactory performance.

#### Handling, Storage, Preservation, Packaging, and Delivery

**Handling, Storage, and Preservation**— Excipient products, intermediates, and raw materials should be handled and stored under appropriate conditions of temperature, humidity, and light so that the identity, strength, quality, and purity are not affected. Storage and handling procedures should protect containers and closures from contamination and deterioration and should prevent mix-ups (e.g., between containers that have different specifications but are similar in appearance).

Raw materials, including solvents, are sometimes stored in silos or other large containers, making precise separation of lots or batches difficult. If such materials are used, this should be noted in an inventory or other record, with reasonable accuracy.

Outdoor storage of raw materials (e.g., acids, other corrosive substances, explosive materials) is acceptable provided the containers give suitable protection to their contents, identifying labels remain legible, and containers are adequately cleaned prior to opening and use.

**Packaging System**— An excipient packaging system should include, at a minimum, the following features:

- Written specifications, examination or testing methods, and cleaning procedures where so indicated.
- Tamper evident seals, particularly if the excipient claims to be sterile or nonpyrogenic or if returned material is to be restocked.
- Evaluation of the container closure system, in which it is demonstrated that there is adequate protection from deterioration and contamination and that the excipient is not altered beyond its established specifications.
- All previous labeling removed or defaced if returnable excipient containers are reused. If the containers are repetitively used solely for the same excipient, all previous lot or batch numbers or the entire label should be removed or completely obliterated.

**Delivery**— The manufacturer should arrange for the protection of the quality of product after final inspection and test. Where contractually specified, this protection should be extended to include delivery to the destination.

Distribution records should be kept that document all shipments of finished products. To facilitate its recall, if necessary, these records should identify by excipient batch or lot where and to whom the product was shipped, the amount shipped, the carrier, and the date of shipment.

#### Quality Record Control

The manufacturer should establish and maintain procedures for identification, collection, indexing, filing, storage, maintenance, and disposition of quality records. Quality records should be maintained to demonstrate achievement of the required quality and the effective operation of the quality system. Pertinent subcontractor quality records should be an element of the data.

All quality records should be legible and identify the product involved. Quality records should be kept for at least as long as samples are retained or in accordance with legislative requirements. These records should be stored in facilities that provide a suitable environment to minimize deterioration or damage and to prevent loss and should be maintained in such a way that they are readily retrievable.

Batch production and control records should be prepared for each batch of excipient produced and should include complete information relating to the production and control of each batch. These records should include an accurate reproduction of the appropriate master production or control record, checked for accuracy, dated, and signed; and documentation that each significant step in the manufacture, processing, packing, or holding of the batch was accomplished, including the following:

- Dates
- Identity of individual major equipment and lines used, and specific identification of each batch of component or in-process material used
  - Weights and measures of components used in the course of processing
    - In-process and laboratory control results
  - Inspection of the packaging and labeling area before and after use
- A statement of the actual yield and a statement of the percentage of theoretical yield at appropriate phases of processing
  - Complete labeling control records, including specimens or copies of all labeling used
    - Description of drug product containers and closures
    - Any sampling performed
  - Identification of the persons performing and directly supervising or checking each significant step in the operation
    - Any investigation made for failures and discrepancies
  - Results of examinations made during final product inspection.

#### Internal Quality Audits

The excipient manufacturer should carry out a comprehensive system of planned and documented internal quality audits to verify whether quality activities comply with planned arrangements and to determine the effectiveness of the quality system. Audits should be scheduled on the basis of the status and importance of the activity. The audits and follow-up actions should be carried out in accordance with documented procedures.

The results of the audits should be documented and brought to the attention of the management personnel having responsibility in the area audited. The management personnel responsible for the area should take corrective action on the deficiencies found by the audit.

#### Training

The excipient manufacturer should establish and maintain procedures for identifying and providing the training needs of all personnel performing activities affecting quality. Appropriate records of training should be maintained. Training should directly relate to the employee's function or performance of specific operations and to good manufacturing practices. This training should be conducted by qualified individuals on a continuing basis and with sufficient frequency to ensure that employees remain familiar with any applicable manufacturing practice requirements.

#### APPENDIX 1. DEFINITIONS

**Active Ingredient:** a substance or bulk pharmaceutical chemical that is intended to furnish pharmacological activity or other direct effect in the diagnosis, cure, mitigation, treatment, or prevention of disease or to affect the structure or any function of the body of man or other animals.

**Adulterated Substance:** a material that has either been contaminated with a foreign substance or not manufactured using good manufacturing practices. This definition does not pertain to materials that do not meet physical or chemical specifications.

**Aseptic:** an environment free from pathogenic microorganisms.

Batch (Lot): a defined quantity of raw material, intermediate material, packaging components, or final product processed so that it is expected to be homogeneous. In a continuous process, a batch corresponds to a defined portion of the production, based on time or quantity (e.g., vessel volume, one day's production, etc.).

Batch Number (Lot Number): a distinctive combination of numbers or letters from which the complete history of the manufacture, processing, packing, coding, and distribution of a batch can be determined.

Batch Numbering System: a standard operating procedure (SOP) describing the details of assigning batch numbers.

Batch Record: documentation that provides the history of a batch from the raw material stage to completion of the batch or lot.

Blending (Mixing): intermingling different conforming grades into a homogeneous lot.

Certificate of Analysis: a document relating specifically to the results of testing a representative sample drawn from the material to be delivered.

Clean Area: an area with defined environmental control of particulate and microbial contamination, constructed and used in such a way as to reduce the introduction, generation, and retention of contaminants in the area.

Commingling: the blending of trace carryover material from one grade of an excipient with another, usually due to a continuous process.

Contaminant: an impurity not intended to be present in an excipient, which may be introduced by poor cleaning, processing, or lack of appropriate environmental and personnel controls during the manufacturing process.

Continuous Process: a manufacturing process that continually produces an excipient from a continuous supply of raw materials.

Critical Process: a manufacturing process step that may cause variation in quality attributes.

Cross-contamination: contamination during production of a raw material, intermediate, or of a finished excipient with another raw material, intermediate, or product.

DMF: detailed information submitted to the United States Food and Drug Administration concerning a specific facility, process, or product intended for incorporation by reference into a new drug application, supplemental new drug application, abbreviated new drug application, or investigational new drug application.

Excipient: any substances, other than the active drug or product, that have been appropriately evaluated for safety and are included in a drug delivery system to either aid the processing of the drug delivery system during its manufacture, protect, support or enhance stability, bioavailability, or patient acceptability, assist in product identification, or enhance any other attribute of the overall safety and effectiveness of the drug delivery system during storage or use.

Expiration Date: the date beyond which the product may no longer conform to relevant specifications.

Finished Dosage Form (Drug Product): a finished pharmaceutical product, prepared for consumer applications, containing excipients and the active drug substance.

Finished Product: any pharmaceutical product that has undergone all stages of production, including packaging and labeling.

Finished Process Materials: any material that has undergone all stages of production and is released from quality control.

Homogeneous Material: throughout the batch, material of uniform consistency and composition.

Impurity: a substance contained in a product other than the desired substance.

In-Process Testing: monitoring checks performed during production to ensure that the product conforms to its specifications.

In-Process Material: any material that must undergo further manufacture before it becomes a bulk product.

Intermediate Product: any material that must undergo further manufacturing steps before it becomes a bulk product.

Lot: See Batch.

Manufacturer: the company that performs the final production steps and release of the product.

Manufacturing Process: all steps necessary to produce a finished product from raw materials.

Master Formula (Master Formula Record): documentation describing the manufacture of the excipient from raw material to completion of the lot or batch.

Material Review Board: a committee or group selected to evaluate the disposition of potentially nonconforming material.

Model Product: a product that simulates a group of like products.

Mother Liquor: a concentrated solution from which the product is obtained by evaporation, freezing, or crystallization.

Re-evaluation Date: that date beyond which the bulk pharmaceutical excipient should not be used without prior adequate re-examination.

Representative Sample: a sample drawn according to an appropriate sampling plan, which may involve regular or random selection.

Reprocessing: introducing back into the process previously processed material that did not conform to standards or specifications and repeating steps that are already part of the normal manufacturing process.

Nonconforming Material: any material that does not meet manufacturer's specifications or applicable good manufacturing practices.

Packaging: the act of filling and labeling a container with a product.

Packaging Material: the containers, closures, and labels employed in the packaging of a product.

Processing Instructions: the manufacturing procedures set forth in the master formula.

Production: all operations involved in the preparation of an excipient pharmaceutical product, from receipt of raw materials through the completion of a finished product.

Purification: the process of removing impurities from a substance.

Quality: the totality of features and characteristics of a product that bear on its ability to satisfy stated or implied needs.

Quality Assurance: all those planned and systematic actions necessary to provide confidence that a product or a service will satisfy given requirements for quality.

Quality Control: all activities such as measuring, examining, testing, or gauging one or more characteristics of a product (including raw materials) and comparing the findings with specified requirements to determine conformity.

Quality Control Instruments: measurement instruments used to monitor the manufacturing process, in-process controls, and the finished excipient products for final quality control approval.

Quarantine: the status of any material isolated physically or by other effective means while awaiting a decision on its use.

Raw Material: any substance used in the production of a product excluding packaging materials.

Reserve (Retained) Sample: a representative sample of the final excipient batch of sufficient quality and quantity necessary to perform quality control analyses twice.

Returned Products: finished products sent back to the manufacturer.

Reworking: introducing previously processed material that did not conform to standards or specifications to processing steps that are different from the normal process.

Significant Processing Step: processing steps that are required to produce an excipient that meets the established physical and chemical criteria.

Shelf Life: the length of time during which the excipient exhibits stability.

Specifications: the quality parameters that serve as a basis for quality evaluation and to which the products or materials must conform.

Stability: the continued conformance of the excipient to its specifications.

Standard Operating Procedures (SOPs): a written authorized procedure that gives instructions for performing operations.

Validation: documentation that states that any procedure, process, equipment, material, or activity consistently leads to the expected results.

Vendor: an organization contracted to supply a material or perform a service.

## APPENDIX 2. GENERAL AUDITING CONSIDERATIONS

### Evaluation

Prevention of Contamination— In evaluating the adequacy of measures taken to prevent contamination of materials in the process, it is appropriate to consider the following factors:

- Type of system (e.g., open or closed. Closed systems in chemical plants are often not closed when they are being charged or when the final product is being emptied. Also, the same reaction vessels are sometimes used for different reactions)
  - Form of the material (e.g., wet or dry)
- Stage of processing and use of the equipment and/or area (e.g., multi-purpose or dedicated)
  - Continuous versus (discrete) batch production.

Other factors that should be considered in evaluating an excipient plant are the degree of exposure of the material to adverse environmental conditions, the potential for cross-contamination from any source, the relative ease and thoroughness of clean-up, and sterile versus nonsterile operations.

Documentation— An excipient manufacturer should recognize the need for appropriate evaluation and utilization of proper standards and test procedures for raw materials before they are introduced into the process. In addition, as chemical processing proceeds, a chain of documentation should be established that includes the following:

- A written process
- Identification of critical processing steps
  - Appropriate production records
- Records of initial and subsequent lot or batch numbers
  - Records of raw materials used
- Intermediate test results with meaningful standards.

The production of some excipients involves processes in which chemical and biochemical mechanisms have not been fully characterized; therefore, the methods and procedures used in their production will often differ from those applicable to the manufacture of finished dosage forms.

It should be recognized that all intermediates need not require testing. An excipient manufacturer should, however, be able to identify critical or key points in the process where selective intermediate sampling and testing is necessary in order to monitor process performance. The records should become more complete as the end of the process approaches.

The finishing steps and packaging steps should be conducted under appropriate conditions to avoid contamination and mix-ups and be appropriately documented.

### Inspections

Inspection of an excipient operation may depend on the purpose of the audit and intended use of the excipient. Operational limitations and validation of the significant processing steps of a production process should be examined to determine that the manufacturer adequately controls steps to ensure that the process performs consistently. Overall, an inspection should determine the excipient manufacturer's capability to deliver a product that consistently meets the specifications listed in the marketed application or the product specifications needed for research purposes. A team consisting of auditors, engineers, laboratory analysts, purchasing agents, computer experts, or other appropriate personnel should participate in the inspection when resources permit. Confidentiality of the manufacturers' processes must be respected by external auditors.

A good starting point for an excipient plant inspection is a review of the following areas.

- Nonconformance—This could be because of the rejection of a lot or batch that did not meet specifications, customer complaints, return of a product by a customer, or recall of a product. The cause of the nonconformance should have been determined by the manufacturer, a report of the investigation prepared, and subsequent corrective action initiated and documented. Records and documents should be reviewed to ensure that nonconformances are not the result of a poorly developed or inconsistent process.
- Complaint files—Customers may report some aspects of product attributes that are not entirely suitable for their use. These may be caused by impurities or inconsistencies in the excipient manufacturing process.
  - Change control logs
  - Material Review Board documents or equivalent team reports
- Master formula and lot or batch production records—Frequent revisions may reveal problems in the excipient production process.
  - Specifications for the presence of unreacted intermediates and solvent residues in the finished excipient
  - Storage areas for rejected products.

### Significant Processing Steps

Significant processing steps are those steps that are required to produce an excipient that meets the established physical and chemical criteria. These steps should be identified by the excipient manufacturer. Significant processing steps can involve a number of unit operations or unit processes. Unit operations include physical processing steps involving energy transfer where there is no chemical change of the molecule. Unit processes include those processing steps wherein the molecule undergoes a chemical change.

Significant processing steps can include, but are not limited to, the following:

- Phase changes involving either the desired molecule, solvent, inert carrier or vehicle (e.g., dissolution, crystallization, evaporation, drying, sublimation, distillation, or absorption)
  - Phase separation (e.g., filtration or centrifugation)
- Chemical changes involving the desired molecule (e.g., removal or addition of water of hydration, acetylation, formation of a salt)
  - Adjustments of the solution containing the molecule (e.g., adjustment of pH)
- Precision measurement of added excipient components, in-process solutions, recycled materials (e.g., weighing, volumetric measuring)
  - Mixing of multiple components
- Changes that occur in surface area, particle size, or lot or batch uniformity (e.g., milling, agglomeration, blending).

### Documentation and Record Keeping

Documentation required for the early steps in the process should provide a chain of documentation, but need not be as comprehensive as in latter parts of the process. The minimum documentation that should be applied in order to promote uniformity in excipient GMP inspections is:

- the assignment of a unique lot or batch number to the released or certified excipient
  - the preparation of a lot or batch record
- demonstration that the lot or batch has been prepared using GMP guidelines from the processing point at which excipient manufacturing practices have been determined to

- apply
- demonstration that the lot or batch is homogeneous within the manufacturer's specifications (This does not necessitate final blending of continuous process material if process controls can demonstrate compliance to specifications throughout the lot or batch.)
    - demonstration that the lot or batch is not commingled with material from other lots or batches for the purpose of either hiding or diluting an adulterated batch
    - demonstration that the lot or batch has been sampled in accordance with a sampling plan that ensures a representative sample of the lot or batch
  - demonstration that the lot or batch has been analyzed using scientifically established tests and methods designed to ensure that the product meets standards, specifications, and characteristics
  - demonstration that an excipient has stability data to support the intended period of use. (These data can be obtained from actual studies on the specific excipient or from applicable model product studies that can reasonably be expected to simulate the performance of the specific excipient.)

Complete documentation should exist when:

- the excipient can be identified and quantified for those processes where the molecule is produced during the course of the process (In this regard, a theoretical yield should be established with appropriate limits, and there should be an investigation if the actual yield falls outside the limits.)
- a contaminant, impurity, or other substance likely to adversely affect the purity or form of the molecule is identified and subsequent attempts are made to remove it
  - any significant aberration occurs outside of the normal manufacturing process.

Complete documentation should be continued throughout the remainder of the process for all significant processing steps until the excipient is packaged and transported to the end user.

#### Product Lot or Batch Consistency and Audit

Excipient manufacturing plants often produce laboratory or pilot lots or batches. Scale-up to commercial production may involve several stages, and data should be reviewed to demonstrate the adequacy of the scale-up process. Scale-up may introduce significant problems in consistency among lots or batches. Pilot lots or batches should serve as the basis for establishing in-process and finished product purity specifications.

Typically, manufacturers will generate reports that discuss the development and limitation of the manufacturing process. Summaries of such reports should be reviewed to determine if the plant is capable of adequately producing the excipient. The reports, where appropriate, serve as the basis for the validation of the manufacturing and control process, as well as the basic documentation to demonstrate that the process performs consistently.

A review of a process flow chart is helpful in understanding the various processing stages. As part of the review of the processing records, the critical stages and sampling points should be identified. The normal limits from in-process testing should be determined, along with the action to be taken by the manufacturer should these specifications not be met. For example, an in-process test result may show the presence of some unreacted material which may indicate that the process time should be extended.

Auxiliary Information— Please [check for your question in the FAQs](#) before contacting USP.

#### 1079 GOOD STORAGE AND SHIPPING PRACTICES

This general information chapter is intended to provide general guidance concerning storing, distributing, and shipping of Pharmacopeial preparations. It describes procedures to maintain proper storage environments for individual articles and to ensure a preparation's integrity, including its appearance, until it reaches the user. There is no change to any applicable requirements under Current Good Manufacturing Practices, approved labeling, state laws governing pharmacies, the USP General Notices and Requirements, or monographs. The section Preservation, Packaging, Storage, and Labeling under General Notices and Requirements provides definitions for storage conditions. All equipment used for recording, monitoring, and maintaining temperatures and humidity conditions should be calibrated on a regular basis. This calibration should be based on NIST or international standards (see [Monitoring Devices—Time, Temperature, and Humidity](#) 1118). A Pharmacopeial preparation may follow several potential routes from the original manufacturer to the patient. [Figure 1](#) documents present-day routes and the associated risks. These risks include exposure to temperature excursions, humidity, light, and oxygen. For a discussion of climates, stability, and mean kinetic temperature, see [Pharmaceutical Stability](#) 1150. Temperature- or humidity-sensitive articles are to be handled in accordance with General Notices.

#### PACKAGING AND STORAGE STATEMENT IN MONOGRAPHS

Most articles have storage conditions identified by their labeling. Otherwise, it is expected that the conditions for storing the article are specified in the monograph according to definitions provided by the General Notices and Requirements in the section Storage Temperature, and Humidity under Preservation, Packaging, Storage, and Labeling. In cases where additional information on packaging and storage is desired, a specific statement can be provided in the Packaging and storage or the Labeling section of the individual monograph.

#### STORAGE IN WAREHOUSES, PHARMACIES, TRUCKS, SHIPPING DOCKS, AND OTHER LOCATIONS

Pharmacopeial articles are to be stored in locations that adhere to conditions established by the manufacturer. Where the desired conditions are not established, use storage conditions described in the General Notices and Requirements or in the applicable monograph.

##### Warehouses

Observation of the temperature variations in a warehouse should be made over a period of time to establish a meaningful temperature profile, including the temperature variations and conditions in the different parts of the warehouse. Such observations provide data and information as to where various products should and should not be stored.

##### establishing temperature profiles

Temperature profiles can be compiled by using a suitable number of thermometers or other temperature recording instruments. They should be placed throughout the warehouse in divided sections and should record the maximum and minimum temperatures during a 24-hour period for a total of three consecutive 24-hour periods. The following factors, some of which may give rise to extreme temperatures, should be considered during the process of temperature profiling: the size of the space, location of space heaters, sun-facing walls, low ceilings or roofs, and geographic location of the warehouse. Temperature profiling for warehouses already in use should be done at known times of external temperature extremes, e.g., for a period of not less than 3 hours when air temperatures are higher than 25° or less than 15°. Profiling should be conducted in both summer and winter. A mean kinetic temperature (MKT) should be obtained for any separate areas within the warehouse (see [Pharmaceutical Calculations in Prescription Compounding](#) 1160 for samples of MKT calculations). The temperature profile report should provide recommendations for the use of each area and identification of any areas that are found unsuitable for storage of Pharmacopeial articles.

##### controlled room temperature

The General Notices provide a definition for Controlled Room Temperature. A temperature profiling study should demonstrate suitability for storing Pharmacopeial articles in areas determined to be at room or controlled room temperature. A suitable number of temperature and humidity recording instruments should be installed to record temperatures and to provide temperature and humidity profiles. Temperature recording should be conducted to meet the recommendations for establishing mean kinetic temperature and to comply with the

warehouse's written procedures. These written procedures should have a reporting mechanism in place whereby a management tree is informed in the event that predefined high or low temperatures or humidity limits have been exceeded. Records can be reviewed as determined by the management system in accordance with established guidelines. Suitable training should be provided to persons who record temperatures, and proper quality accountability and tracking systems should be maintained.

storage at "cool," "cold," "refrigerator," and "freezing" conditions

The General Notices provide definitions for cool, cold, refrigerator, and freezer temperatures. A temperature profiling study can be used to establish suitable areas for storing Pharmacopeial articles designated to be stored under these conditions. Equipment used for storing Pharmacopeial articles at these low temperatures should be qualified according to written procedures provided by the management system. Recording devices can be installed within the equipment and used to enable both air and product temperatures to be recorded at regular intervals. The number and location of monitoring devices should be determined based on the result of the temperature profile. Temperature records should be examined at least once every 24 hours or as provided in the equipment protocol. Cool or cold conditions are moisture-condensing conditions. Humidity-monitoring devices should be used in cases where the repackaged Pharmacopeial article is humidity-sensitive or labeled to avoid moisture. Additionally, there can be installed temperature-monitoring, and where necessary, humidity-monitoring alarm devices that have the capability of alerting personnel in the event that control is compromised. There should be protocols in place to address procedures for responding to failed temperature and humidity ranges both for normal working hours and outside normal working hours. Temperature and humidity should be reviewed

at the times designated by the established protocol. The calibration and functioning of all temperature and humidity monitoring devices, including alarms and other associated equipment, should be checked on an annual or semiannual basis. Regular maintenance protocols should be in place for refrigeration equipment. There should be written agreements in place for all maintenance and evaluation procedures, and this may include an emergency situation protocol.

#### personnel training

Suitable training should be provided for personnel who handle Pharmacopeial articles with special storage temperature requirements. Personnel should know how to monitor temperatures and how to react to situations where adverse temperatures are identified. There should be written procedures in place such that the adverse temperatures are recorded and a report provided to the parties designated in the protocol.

#### qualification of "cold" equipment or stores

Only climate control equipment for which a contractor has provided documentation to assure its suitability for temperature and humidity requirements should be considered for use in cold storage. Qualification procedures on a regular basis should be independently conducted on equipment in cold stores to guarantee suitability and proper functioning. The procedure should demonstrate the temperature profile for both air and product temperatures when empty as well as when loaded. The procedure should also demonstrate the time taken for temperatures to exceed the maximum temperature in the event of a power failure. Qualification should consider thermal fluctuations that occur during stock replenishment and order removal. The results of the qualification should demonstrate the ability of the equipment to maintain the required temperature range in all areas, defining any zones which should not be used for storage such as those areas in close proximity to cooling coils, cold air streams from equipment ventilation, or doors. The variability of the system can be characterized by using the relative standard deviation. Thermal monitoring should establish that the system is rugged in that its temperature profile is consistent and reliable.

### DISTRIBUTION AND SHIPMENT OF PHARMACOPEIAL ARTICLES

As indicated in [Figure 1](#), a drug can take a variety of paths from the manufacturer to the patient. In the simplest form of the distribution system, the manufacturer ships directly to the customer, such as a doctor's office, clinic, or hospital. However, more often, the article leaves the manufacturer's chain of control and enters a complex system of handoffs that involve the distribution chain to the patient.

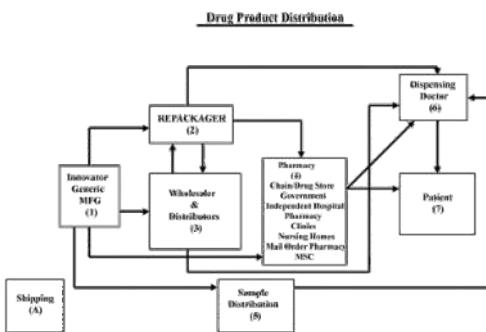

Figure 1. Drug product distribution.

Shippers and distributors are to follow the proper storage and shipping requirements as indicated by the manufacturer. For particular cases, such as shipment of vaccines or other special care products, manufacturers may require special shipping and storage conditions generally referred to as "cold-chain management". For example, manufacturers may attach temperature-monitoring devices and/or ship under specified controlled conditions to ensure that the desired temperature is maintained during distribution (see [Monitoring Devices—Time, Temperature, and Humidity](#) [1118](#)). Validated, available temperature- and/or humidity-monitoring technologies can be used to monitor the overall environmental effect on compendial articles during shipment and distribution. In these cases, the shipping conditions of the package are recorded. In general, extreme temperature conditions (i.e., excessive heat, freezing) should be avoided. Distribution systems chosen to deliver pharmaceutical products from the manufacturer to the consumer should take into account basic operational parameters, including timeliness and accountability. The manufacturer's FDA-approved storage conditions, printed in the labeling of the product, should be observed carefully at each destination of the distribution chain (see [Figure 1](#)), unless specifically instructed otherwise in the immediate label of a shipping container. This may be the case for certain pallet-sized shipping containers where the amount of refrigerant contained (e.g., dry ice, gel packs) is based on an anticipated exterior condition approximating controlled room temperature. In such cases, placing the shipping container in a refrigerator could lead to the product inside freezing, potentially affecting its quality. Items requiring special handling conditions will have those conditions clearly indicated in the labeling for the product. The Prescription Drug Marketing Act of 1987 and the ensuing regulations in 21 CFR Part 203, Prescription Drug Marketing, and Part 205, Guidelines for State Licensing of Wholesale Prescription Drug Distributors, provide the necessary regulations and guidance for several legs of the distribution chain for the prescription drug. The manufacturers and distributors should work together to establish proper distribution and product-handling requirements for the purpose of ensuring appropriate product maintenance in transit. Pharmacists and physicians should educate patients regarding proper storage of products to ensure product integrity at the patient level. Information that may be considered in determining the ability of pharmaceutical articles to maintain their Pharmacopeial requirements of identity, strength, quality, and purity through the distribution channel may include, but is not limited to the following: ICH stability studies, temperature cycling studies, stability shipping studies, ongoing regulatory stability commitment studies, market experience portfolio (i.e., product complaint files, historical product performance data, product development data), and product labeling commitments.

#### Qualification Protocol

Operational and performance testing should be parts of a formal qualification protocol that may use controlled environments or actual field testing based on the projected transportation channel. These should reflect actual load configurations, conditions, and expected environmental extremes. Temperature and humidity monitors should be placed into the product or a representative thereof. Testing consists of consecutive replicate field transportation tests using typical loads, according to an established protocol.

#### Physical Challenges

Most products are sufficiently robust to withstand distribution with minimal protection from routine, well-understood physical and environmental hazards. Several standard test methods are available for evaluating package performance factors under well-documented shock, vibration, and other transit elements. The American Society for Testing and Materials document, "Standard Practice for Performance Testing of Shipping Containers and Systems" (ASTM D4169-98), and the International Safe Transit Association's (ISTA) specifications have similar methods for evaluation of shipping performance for various types of transit modes such as less-than-truckload (LTL), small package, rail car, air freight, etc. From the

Manufacturer's perspective, these tests are very useful in evaluating the product and package durability and fragility. The tests are usually performed on shipping carton quantities or specific stock keeping unit (SKU) as an unbroken whole. Fragility problems can be corrected with package modifications, which could include placing cotton or rayon colers in bottles or placing top and bottom pads in the shipping case to reduce package breakage. Not all protective packaging elements follow the SKU through the system.

Basic packaging principles are observed when separating the contents of the manufacturer's shipping container or pallet load into smaller quantities or when shipping mixed product loads. For example, glass containers are wrapped in a bubble wrap or other shock-absorbent material, and the void spaces are filled with dunnage (e.g., foam "peanuts," shredded or tightly crumpled paper, bubble wrap) to protect the contents from shifting and drop impact. Large-volume liquid containers may be bagged in plastic and kept isolated to prevent leakage to, or damage of, adjacent packages. "Skin packaging," a term describing a heat-shrink film that anchors the load to fiberboard and prevents load shift, can be an excellent method of protecting some products, but it may be inappropriate for heat-sensitive products. The shipping carton should have correct Edge Crush Test (ECT) characteristics for freight being shipped according to Item 222 of the National Motor Freight Classification and Rule 41 of the Uniform Freight Classification.

#### Temperature Challenges

Shipping of temperature-sensitive articles requiring thermally controlled packaging presents a special challenge. Unlike shock, vibration, and other physical hazards, thermal hazards tend to be unique to a given system. Except for temperature-controlled trucks, the distribution environment is widely variable and depends upon a range of factors, including points of origin and destination, article and container sensitivities to cold, accidental freezing or heat, transit mode (e.g., air, truck, combination), time, weather or season, and carrier type (e.g., small package carrier or integrator, freight forwarder, U.S. Postal Service). The shippers should know and understand the systems they use and should design the protective package accordingly. Storage temperature ranges may not be indicative of the allowable tolerances during shipping. Articles labeled for special storage conditions (between 2° and 8°) vary widely in their tolerance of short-term exposure to heat and cold. Some, such as soft gelatin capsules and suppositories, carry specific upper limits on both shipping containers and SKUs. A temperature cycling study intended to identify those articles affected by multiple, short-term excursions beyond the storage temperature limits should be performed. These data provide wholesalers and distributors with clearer identification of those drug products that may require special handling during particular climate conditions.

#### Materials

Two commonly used types of refrigerant are dry ice (frozen carbon dioxide gas) and wet ice (frozen water), which appears as crushed ice or in various refrigerant packs containing water mixtures with specific freezing points. Phase-change materials are also available for specialized needs. Refrigerant packs should have the correct freezing point and be cooled to the proper surface temperature prior to use. Articles harmed by accidental freezing may require a barrier between the refrigerant and the product or some other special packaging. Insulating materials commonly available include foil laminates, bubble pack, corrugated, fabricated, and molded expanded polystyrene (EPS) cartons, and fabricated or molded urethane foam cartons, with or without additional interior components. Recognized standard test methods for evaluating insulated containers are currently limited to ASTM D3103-92, Standard Test Method for Thermal Insulation Quality of Packages and a method under development by ISTA. Neither one fully addresses all of the issues involved, but both include useful information on testing procedures. The tests should be modified based on the specific system adopted by the shipper. The manufacturer may be able to supply helpful data on specific articles and their requirements.

#### SPECIAL HANDLING

Certain classes of Pharmacopeial articles may require special handling. Such articles include products classified as dangerous goods under the Department of Transportation (DOT), state, local, or carrier rules; or products classified as controlled substances by the Drug Enforcement Administration (DEA) or by individual states.

#### Receipt of Pharmacopeial Articles

Upon arrival of Pharmacopeial articles to warehouse loading docks, premises, and other arrival areas, the Pharmacopeial articles are to be transferred to their manufacturer-designated storage environment within 2 hours of receipt. Limitation of the time spent in the uncontrolled environments of the loading dock is important to ensure that the integrity of the preparation is maintained. This is particularly important for temperature-sensitive items. The delivery document should be reviewed at receiving sites to ensure that the Pharmacopeial articles have not been subjected to any delays during shipment that could result in exposure of the article to extremes of temperature, or to any other extreme or undesirable conditions. In addition, to the extent possible, the receiving personnel should ensure that the ruggedness requirements in shipment have been met. For Pharmacopeial articles requiring extreme caution, special handling, or refrigerator temperature storage conditions, those who supply the articles (e.g., wholesalers and manufacturers) and delivery contractors should provide documented evidence to show that the required temperature range has been maintained during transportation. In the event that a deviation from the required temperature range has been observed during shipment of an article requiring such a shipping condition, the supplier or delivery contractors should document the temperature and the length of time the compendial article was not within the designated storage temperature. The pharmaceutical manufacturer may be contacted to determine the significance of unusual variances.

#### Distribution or Shipping Vehicles

Vehicles used for shipping or distribution of Pharmacopeial articles designated for storage at controlled room temperature should be suitably equipped to ensure that the temperature excursions encountered are within those allowed under the definition of controlled room temperature. Steps should be taken so that extremes of temperature, whether above or below the specified temperatures, should not be encountered during delivery procedures.

#### Vehicle Qualification

Where practical, suitable monitoring devices, as determined by the manufacturer and vehicle supplier, should be placed in different areas of the truck to establish a temperature profile of the truck over a 24-hour period during a hot summer day, average high, and a cold winter day, average low, and during a normal or typical day. The derived temperature of the different parts of the truck may be used to determine the location on the truck where Pharmacopeial articles can be stored appropriately during shipping (see [Monitoring Devices—Time, Temperature, and Humidity \(1118\)](#)).

#### Pharmaceutical Delivery Staff

As part of the contractual agreement between the delivery contractors and the manufacturers, the delivery staff should receive appropriate training to ensure that they are aware of the correct procedures to follow in maintaining products at the correct temperature. There may be written procedures that should be documented. In addition, the transportation personnel should have proper knowledge of the temperature profile of the vehicle to ensure proper placement of the Pharmacopeial articles in the vehicle. Pharmacopeial articles requiring special handling (e.g., refrigeration) or environmentally sensitive preparations should be transported in a suitably equipped vehicle to ensure that the articles are maintained at the correct temperature during distribution, shipping, and delivery and up to the point of receipt. Special arrangements should be made to inform receiving personnel, pharmacists, or other appropriate customers that the package includes articles with special storage and handling specifications and are to be transferred immediately to the appropriate storage location. The manufacturer, shipper, or delivery agency should provide appropriate evidence to show that the required temperature has been maintained throughout shipment and distribution.

#### SHIPMENT FROM MANUFACTURER TO WHOLESALER

##### Wholesaler

The wholesaler receiving the pharmaceutical articles should ensure that on arrival, the pharmaceutical articles are transferred to the correct environment without delay, as directed by the manufacturer, ideally within 2 hours of receipt. The wholesaler should examine the delivery documentation to ensure that the products have not been subjected to any delays during shipping and distribution that could result in products being exposed to extreme temperatures (see also the previous section, Pharmaceutical Delivery Staff, for staff expectations). The vehicles used for shipping of Pharmacopeial articles to the wholesaler, especially products requiring storage at low temperatures, should be suitably equipped to ensure that products are maintained at the correct temperature during shipping and distribution and up to the point of receipt. The receiving wholesaler staff should be informed that the articles are transferred to appropriate storage locations without delays. The vehicles used for shipping of Pharmacopeial articles requiring storage at room or controlled room temperatures should be suitably equipped to ensure that extremes of temperature, either above or below the specified temperature, do not occur during delivery procedures. Warehouse staff may receive appropriate training to ensure that the correct procedures are followed to maintain required temperature conditions (see Pharmaceutical Delivery Staff). Where necessary, a monitoring device for temperature and/or humidity should be used during shipping and distribution.

#### Compromised Temperature Conditions

A procedure should be in place in the warehouse to define the action that should be taken in the event of deviation from required storage conditions. Suitable records should be maintained to explain the reason for deviation and the resulting action that is taken. The product in question should then be placed in a quarantine status. Advice on the suitability of the product for use should be sought from the manufacturer or supplier of the product. The manufacturer's response should be documented prior to issuing the product to the customer, if that product is to be issued to the customer.

#### SHIPMENT FROM MANUFACTURER OR WHOLESALER TO PHARMACY

##### Pharmacy

The pharmacy receiving the pharmaceutical articles should ensure that on arrival, the pharmaceutical articles are transferred to the correct environment without delay, as directed by the manufacturer, ideally within 2 hours of receipt. The pharmacy personnel should examine the delivery documentation to ensure that the products have not been subjected to any delays during shipping and distribution, which could result in the products being exposed to extreme temperatures (see also the section, Pharmaceutical Delivery Staff, for staff expectations). The vehicles used for shipping of Pharmacopeial articles to the pharmacy, especially products requiring storage at low temperatures, should be suitably equipped to ensure that products are maintained at the correct temperature during shipping and distribution and up to the point of receipt. Receiving pharmacy staff should be informed that the articles are to be transferred to appropriate storage without delays. The vehicles used for shipping of Pharmacopeial articles requiring storage at room or controlled room temperatures should be suitably equipped to ensure that extremes of temperature, either above or below the specified temperature, do not occur during delivery procedures. Pharmacy staff may receive appropriate training to ensure that the correct procedures are followed to maintain required temperature conditions (see Pharmaceutical Delivery Staff). Where necessary, a monitoring device for temperature and/or humidity may be used during shipping and distribution.

#### Compromised Temperature Conditions

The pharmacy should maintain appropriate procedures to define action that should be taken in the event of deviation from the required storage conditions. Suitable records should be maintained to explain the reason for deviation and the resulting action taken (including whether the product is issued to the patient or customer). Advice on the suitability of the product for use as an acceptable drug article should be sought from the manufacturer or supplier of the product.

#### SHIPMENT FROM PHARMACY TO PATIENT OR CUSTOMER

The pharmacy should provide an appropriate label on the package sent through air or surface routes so that the deliverer does not place the package in a mailbox exposed to extremes in temperature. In the event that no one is available to receive the package, the deliverer should return the package to the post office or service office, and store it in a cool or air-conditioned area until the patient can receive the medication. In the event that the package has not been delivered for more than 2 days, the package may be returned to the pharmacy. For temperature-sensitive articles, it is important that proper arrangements be made to protect the drug from exposure to high temperatures, or in some cases, from freezing conditions. Such arrangements may include the following: insulating the packaging, or packaging with coolant included; overnight shipping; and pre-arranged pick-up. In such cases, the pharmacy should provide on the external package a statement of an acceptable period of delay for delivery. The patient or customer should examine the delivery documentation to ensure that the package has not been subjected to any unacceptable delays during shipping and distribution. The patient or customer receiving the pharmaceutical articles, either by mail, delivery vehicle from the pharmacy, or directly from the physician or pharmacy, should be advised that upon receipt the articles are to be transferred to appropriate storage conditions without delay, as directed by the pharmacy, ideally within 2 hours of receipt. The vehicle used for air or surface shipping and distribution of pharmaceutical packages to the patient or customer, especially those requiring low temperatures, should contain the article suitably packaged in containers that maintain the desired storage conditions until the article reaches the patient or customer. The vehicles used for shipping and distribution of pharmaceutical articles to patient or customer, especially those requiring storage at room or controlled room temperatures, should be suitably equipped during extreme temperature conditions such that the packages are not exposed to extremes of temperature either in winter or summer months. In the event that the vehicle is not adequately equipped with air conditioning or heating to protect the product, the time that the article is exposed to ambient conditions should be strictly limited, ideally not more than 2 hours. Where appropriate, a monitoring device may be used to ensure that required temperatures are maintained until the package reaches the patient or customer. If stability studies for the Pharmacopeial preparation indicate that it is particularly sensitive to environmental insults or if appropriate shipping safeguards described in this section are not feasible, then the preparation should be shipped by a different method whereby environmental control can be maintained.

#### Compromised Temperature Conditions

There should be appropriate procedures in the pharmacy that ships the article to the patient or customer defining the action that should be taken in the event that a patient reports that there has been a deviation from required storage conditions for an article, including any environmentally sensitive preparations, prior to the point of receipt. Advice on the suitability of the product for use should be provided to the patient or customer after the manufacturer or supplier's advice has been sought by the pharmacy. If the patient is advised to use the article, such advice should be documented and noted appropriately by the pharmacy. Otherwise, appropriate arrangements should be made to promptly replace the suspect article. For mail order items, replacement from local pharmacies may be an option to ensure an uninterrupted supply of medication.

#### RETURNS OF PHARMACEUTICAL ARTICLES FROM PATIENTS OR CUSTOMERS

The wholesaler, manufacturer, and pharmacy personnel should evaluate the validity of the request for return, and maintain an auditable account of the return receipt. For products in unopened manufacturer's containers that have been at variance during shipment, arrangement may be made to return the products to the manufacturer, wholesaler, or pharmacy preferably within 3 working days of receipt. The supplier may request records or written confirmation by the patient to show that the product was stored properly while in possession of the customer.

#### STORAGE OF PHYSICIAN SAMPLES HANDLED BY SALES REPRESENTATIVES IN AUTOMOBILES

Storage of physician samples by sales representatives is regulated under 21CFR 203.34(b)(4); each manufacturer or distributor is to have appropriate policies in place to ensure that proper storage is maintained. The following suggestions may be considered in response to this need and are of interest to practitioners who may observe actual practices. Automobile trunks or passenger cabins used for the storage and distribution of physician samples should be monitored to determine the temperature profile of the trunk or passenger cabin. Suitable monitoring devices as determined by the sales representative may be placed in different areas of the trunk or passenger cabin on a hot summer and a cold winter day. Measurements should also be made during typical 24-hour periods, and the derived temperature should be used for calculation of the mean kinetic temperature at which the sample is stored (see [Pharmaceutical Calculations in Prescription Compounding](#) (1160) for examples of MKT calculations). If the Pharmacopeial article designated for storage requires storage at controlled room temperature, then suitable measures should be taken to maintain the sample within the allowable limits of the storage parameters. Environmentally-sensitive preparations should not be stored in automobile trunks or passenger cabins. Medications stored in automobile trunks or passenger cabins should be removed at the end of 3 days. Sales representatives should consider parking automobiles in shaded areas to avoid extreme heat during the summer and in garages to avoid freezing temperatures during the winter. The use of vouchers from the manufacturer that patients could use to obtain medication samples from participating pharmacies is an alternative way of providing drug samples.

#### STABILITY, STORAGE, AND LABELING

The design of stability studies of Pharmacopeial articles is based on knowledge of the behavior, properties, and stability of the drug substance and experience gained from clinical formulation studies.<sup>3</sup> The length of the studies and the storage conditions for a Pharmacopeial article should be sufficient to cover storage, shipment, distribution, and subsequent use of a Pharmacopeial article. The data gathered from ICH accelerated testing or from testing at an ICH intermediate condition may be used to evaluate the effect of short-term excursions outside the label storage conditions such as those that might occur during shipping. See [Pharmaceutical Stability](#) (1150).

#### STATEMENTS/LABELING OF THE IMMEDIATE CONTAINERS OR PACKAGE INSERT

Storage statements should be based on the stability evaluations of the Pharmacopeial drug substances and in accordance with national and international requirements.

Temperature Storage Statements— For products with a storage statement reading, "Store at controlled room temperature," the labeling should read as follows on the package insert: "Store at 20°C to 25°C (68°F to 77°F), excursions permitted between 15°C and 30°C (between 59°F and 86°F). Brief exposure to temperatures up to 40°C (104°F) may be tolerated provided the mean kinetic temperature does not exceed 25°C (77°F); however, such exposure should be minimized."

On the immediate container label, the following may read for controlled room temperature (CRT): "Store at 20°C to 25°C (68°F to 77°F), excursions permitted between 15°C and 30°C (between 59°F and 86°F)."

Cool Storage Statement— The storage statement for labeling may be as follows: "Store in a cool place, 8°C to 15°C (46°F to 59°F)."

Refrigerator Storage Statement— The storage statement for labeling may be as follows: "Store in a refrigerator, 2°C to 8°C (36°F to 46°F)."

Freezer Storage Statement— The storage statement for labeling may be as follows: "Store in a freezer, -25°C to -10°C (-13°F to 14°F)."

See the General Notices for all other applicable storage conditions, such as Storage Under Nonspecific Conditions and store in a Dry Place. Additional cautionary statements to protect the Pharmacopeial drug product from extreme temperature and humidity conditions may be included on the container label and package insert, as the manufacturer desires.

## 1080 BULK PHARMACEUTICAL EXCIPIENTS—CERTIFICATE OF ANALYSIS

### BACKGROUND

This general information chapter is derived from the Certificate of Analysis Guide for Bulk Pharmaceutical Excipients, prepared by The International Pharmaceutical Excipients Council of the Americas (IPEC-Americas), an international guidance document on the preparation and appropriate use of a Certificate of Analysis (COA) for these excipients, referenced throughout the chapter as "excipient(s)". The chapter defines the suggested elements of a Certificate of Analysis, provides a template for organizing required and optional data in a logical manner, and assists in establishing a uniform understanding of the roles and responsibilities of excipient manufacturers, distributors, and users.

The principles and information in this chapter can be applied to the manufacture of all bulk pharmaceutical excipients intended for use in human drugs, veterinary drugs, and biologics. As an international guidance document, it cannot specify all national legal requirements nor cover in detail the particular characteristics of every excipient. When considering how to use this chapter, each manufacturer, distributor, or user should consider how it may apply to that specific manufacturer's product and processes. The diversity of excipients means that some principles of the chapter may not be applicable to certain products and processes.

The chapter is divided into several parts. The first part provides background discussion necessary for the design and suggested elements of a COA. A template is provided to show the format and placement of information in the COA. This is followed by a detailed discussion to ensure that the purpose and meaning of the specific information contained in the COA is understood. For a list of terms used in this information chapter and their definitions, see Appendix 1.

### GENERAL GUIDANCE

International regulations governing drugs require that components of the drugs be manufactured, processed, packed, and held in accordance with good manufacturing practices (GMPs). For a thorough discussion of GMPs that apply to excipient manufacture, see [Good Manufacturing Practices for Bulk Pharmaceutical Excipients](#). The excipient is often a natural substance, mixture, or polymer whose chemical and physical properties are difficult to quantify and that is often used with a broad range of active pharmaceutical ingredients and in a diverse range of finished dosage forms. Until now, there were no guidance documents that specifically focused on the content or format of COAs for excipients and that addressed the diversity of both the excipients and their usage.

**Preparation and Appropriate Use of a Certificate of Analysis—** The Certificate of Analysis for excipients should be prepared and issued by the supplier of the material, following the general guidelines discussed below. Primary responsibility for the preparation of the COA belongs to the excipient manufacturer. It is most important that a complete and accurate COA be provided to the excipient user for specific lots or batches intended for use in the pharmaceutical industry. Additional considerations should be made for the preparation and issuance of a COA by a distributor of excipients.

The user of a bulk pharmaceutical excipient should always receive a COA for material to be used in the manufacture of a drug product. At a minimum, the user should perform adequate identification tests on each lot of excipient received before releasing it for use in the drug product. Specific identity tests should be used whenever possible. It is a regulatory requirement that excipients be assessed for conformity with all appropriate specifications. However, testing of all specification parameters may not be required for lot release if adequate compliance assurances are provided on the supplier's COA. Before using an excipient in a pharmaceutical product based on COA data, the user also should have an understanding of the supplier's control systems and compliance with GMPs, through appropriate auditing or qualification of the supplier.

Nevertheless, it is the responsibility of the user of the excipient to verify any of the analytical data contained in the COA if knowledge of such information is deemed essential to the use of that excipient. Such testing may go beyond the scope of the compendial methods described in the NF, or beyond those used to develop the information in the COA.

To use test results from a COA, the user must also establish the reliability of the supplier's COA test results by periodically performing all required tests and comparing the results obtained to the supplier's test results. Occasionally, it may not be possible to perform all the required tests because of special equipment requirements, etc., that may not be available to the user. Performing fewer than all these tests may be acceptable provided that the reliability of the supplier has been adequately determined using other appropriate supplier qualification techniques.

It is important to understand that these results may not always specifically correlate, especially when an excipient is produced as a continuous lot. However, the user's test results should demonstrate compliance with the specification requirement.

**Use of Contract Facilities—** Contract facilities are frequently used in the manufacture, testing, and distribution of excipients. When such facilities are used, the supplier of the excipient has the obligation to ensure that the facilities operate under appropriate quality standards (i.e., cGMP, GLP, etc.).

### DESIGN AND SUGGESTED ELEMENTS OF A CERTIFICATE OF ANALYSIS

The suggested elements of a COA are listed below and are included in the following Certificate of Analysis Template section of this chapter. Excipient suppliers may organize the suggested elements presented in the COA template at their discretion; however, the parts of the template were designed to present the suggested and optional information in a logical manner. For a detailed description of each element and examples of statements, see the appropriate section below in this chapter.

The origin and the identity of the excipient are typically established in a Header section. The manufacturer and manufacturing site should be identified if different from the supplier and supplier location, enabling the user to make certain that the excipient comes from a qualified source. Although the manufacturer should be made known to the user, the use of codes for manufacturers and manufacturing sites on the COA to protect confidentiality is acceptable. The identity of the excipient must be definitively established by stating the compendial

and trade name, the grade of the material, and applicable compendial designations.

A lot/batch number or other means of uniquely identifying the quantity of material covered by the COA and information relating specifically to it are typically included in a Body section. The lot number or other unique identification of the material, its date of manufacture, and product code or number should be stated and traceable to a specified lot. If applicable, the expiration date, recommended re-evaluation date, or other relevant statement regarding the stability of the excipient is typically included in this section. Any information required by the customer would also be included here.

The actual test results applicable to the quantity of material covered by the COA are included in an Analysis section. The test name, the result, the acceptance criteria or specifications, and a reference to the test method used should be included for each characteristic listed. Reporting of actual data and observations is recommended rather than nonspecific "passes" or "conforms" statements. If the reported results are derived from a skip-lot or reduced frequency testing program, or an average or in-process test result, this should be noted on the COA.

The Certification and Compliance Statement section is used to list various types of statements that may be required depending on the excipient and specific user needs. These statements are usually negotiated between supplier and user based on specific application requirements. Any declaration of the supplier that includes compliance of additional compendial or other regulatory requirements is typically included in this section.

Many excipients have applications other than pharmaceuticals, such as food, cosmetics, or industrial products. Any product listed as being in compliance with specific regulations should meet the specifications and requirements of that regulation and must be manufactured under appropriate GMPs.

The identity of the individual approving the content of the COA should appear on the COA. The page number and total number of pages should also appear on the COA. This information is usually included in a Footer section.

#### CERTIFICATE OF ANALYSIS TEMPLATE

Listed below is a template for the content and format of a COA.

##### Header

- Titled "Certificate of Analysis"
- Company Name, Address, Phone Number, and Identity of Manufacturer and Manufacturing Site
  - Name (compendial/trade) of Excipient
  - Grade of Excipient
  - Compendial Designation

##### Body

- Lot/Batch Number
- Date of Manufacture
- Product Code or Number
- Expiration Date (if required)
- Recommended Re-Evaluation Date (if required)
  - Stability Statement (if required)
  - Customer Required Information

##### Analysis

- Test Name
- Test Results
- Acceptance Criteria (i.e., specifications)
  - Reference to the Test Method
- Reference to Skip-Lot Testing (if appropriate)
- Reference to Average or In-Process Test Results (if appropriate)
  - Date Retested (if appropriate)
  - Summary of Noncompendial Testing (if any)

##### Certification and Compliance Statements

- GMP Compliance
- Additional Regulatory References
- Potential to Meet Additional Compendial Standards
- Content Listing and Grade of Ingredients (if a mixture)
- Other Specific Compliance Statements [e.g., organic volatile impurities (OVI), residual solvents, transmissible spongiform encephalopathy (TSE), etc.]

##### Footer

- Identity of Authorized Individual for Approval
  - Date of Approval
  - Page Number (i.e., 1 of \_\_)

#### COMPENDIAL DESIGNATION

For a supplier to claim a compendial grade on the COA for an excipient, two requirements should be met. The first requirement is that the excipient be manufactured according to recognized principles of GMPs (see General Notices and Requirements). Adequate conformance to GMPs should also be demonstrated for subsequent steps in the distribution of the excipient. The second requirement is that the excipient meet all the specifications contained in the appropriate compendial monograph, unless its difference is stated on its label, as defined under General Notices and Requirements. When an excipient is listed as compendial grade, it is understood that the above requirements have been met for the material, and the user would be able to confirm this through an appropriate audit of the supplier.

Compendial standards define what is considered an acceptable article and also give test procedures that demonstrate that the article is in compliance. These standards apply at any time in the life of the article from production to consumption. The supplier's release specifications and compliance with GMPs are developed and followed to ensure that the article, when stored according to recommended conditions, will comply with compendial standards until its expiration or recommended re-evaluation date.

Every compendial article shall be so constituted that when examined in accordance with these assay and test procedures, it meets all the requirements in the monograph defining it, as well as meeting any provisions under General Notices and Requirements and in the general chapters, as applicable. However, it is not to be inferred that application of every analytical procedure in the monograph to samples from every production batch is necessarily a prerequisite for ensuring compliance with compendial standards before the batch is released for distribution.

Data derived from manufacturing process validation studies and from in-process controls may provide greater assurance that a batch meets a particular monograph requirement than analytical data derived from examination of finished units drawn from the batch. On the basis of such assurances, the analytical procedures in the monograph may be omitted by the supplier when judging compliance of the batch with the compendial standards.

#### DATES ON A CERTIFICATE OF ANALYSIS

Part of the overall goal to standardize COA for excipients includes a provision for the consistent reporting of appropriate, meaningful, and well-defined dates. The discussion below indicates specific dates that are expected on the COA, along with definitions of the dates, in order to provide suppliers and users of excipients with a mutual understanding of their meaning. Use of the recommended terminology will be helpful in reducing the number of questions on dating information reported for excipients. Use of terminology other than that discussed below is discouraged, because the terms may be ill-defined and have different meanings for the excipient supplier and user. Examples of such terms that should not be used include "shelf life", "use-by date", "warranty date", and "expiration period".

In reporting dates on COA for excipients, it is important that a clear and unambiguous format be used to prevent possible misinterpretation. To accomplish this, it is recommended that an alpha designation be used for the month (may be abbreviated), rather than a numerical representation. It is also recommended that the year include all 4 digits (e.g., Jan. 1, 2005, or 1 Jan. 2005).

**Date of Manufacture**— The date of manufacture should be included on the COA for each excipient lot and should be assigned by the suppliers on the basis of their established policies and procedures. It is recognized that excipients may be manufactured using a variety of processes (e.g., continuous or batch) that may require a period of several days or more to complete. In addition, some excipients may be mixtures or blends of other excipients, and excipient production may include reprocessing steps. Because of this diversity, the date of manufacture should be clearly defined by the supplier and consistently applied for the particular excipient and process. In reporting the date of manufacture, the excipient supplier should indicate the date of completion of the final manufacturing process (as defined by the supplier).

It is important to note that repackaging alone is not considered a processing step to be used in determining the date of manufacture. To provide traceability for a specific excipient lot, other dates may be required in addition to the date of manufacture in order to reflect additional steps such as repackaging.

**Expiration Date and Recommended Re-Evaluation Date**— The stability of excipients may be an important factor in the stability of the finished pharmaceutical dosage forms that contain them. Many excipients are very stable and may not require extensive testing to demonstrate continued conformance to appropriate specifications. Other excipients may undergo chemical, physical, and microbiological changes over time that cause the material to fall outside established specifications.

Appropriate expiration and/or recommended re-evaluation dates for excipients should be established from the results of a documented stability-testing program or from historical data. The testing program should include defined and controlled storage conditions (e.g., temperature and humidity), a consideration of different packaging types that may be used as market containers, and meaningful, specific test methods to adequately assess the stability characteristics of the excipient. Stability testing should determine whether possible degradation, moisture gain or loss, viscosity changes, or other possible changes occur to make the excipient unacceptable for use (e.g., unstable or hygroscopic materials). For additional information on excipient stability, see [Good Manufacturing Practices for Bulk Pharmaceutical Excipients](#) (1078).

The expiration date for an excipient is defined as the date after which the supplier recommends that the material should not be used. Prior to the assigned expiration date, the excipient is expected to remain within established specifications, if stored according to the supplier's recommended conditions.

The recommended re-evaluation date for an excipient is the date suggested by the supplier after which the material should be re-evaluated to ensure continued compliance with specifications. Re-evaluation of the excipient may include physical inspection and appropriate chemical, physical, and microbiological testing. Prior to the re-evaluation date, the excipient is expected to remain within established specifications, provided it has been stored according to the supplier's recommended conditions. But beyond the recommended re-evaluation date, the excipient should not be used without adequate evaluation at appropriate intervals, to determine whether the material continues to be acceptable for use. The recommended re-evaluation date differs from the expiration date in that the excipient may be re-evaluated to extend the length of time the material may be used, if supported by the results of the evaluation and appropriate stability data.

In reporting the expiration and recommended re-evaluation dates, the excipient supplier is providing important information to the user about the stability of the material. As discussed previously, the assignment of an expiration date and a recommended re-evaluation date should be based on appropriate evaluation of potential changes that may occur in the material's properties. It is acceptable to report both an expiration date and a recommended re-evaluation date on the COA for excipients, if applicable, but both dates may not always be required. Expiration and recommended re-evaluation dates should not be reported by a supplier without sufficient stability data or product history to support the assigned dates.

For excipients determined to be very stable (greater than 2 years), either the specific expiration date and/or the recommended re-evaluation date should be reported on the COA for the material, or a general stability statement may be included (e.g., stability greater than 2 years). If available data indicate that an excipient has limited stability (2 years or less) under anticipated storage conditions, a specific expiration date and/or recommended re-evaluation date should be reported on the COA for the material.

If data from formalized stability studies are not available for an excipient, an appropriate statement should be included on the COA to indicate what is known about the stability of the material and whether stability studies are in progress.

**Date Retested**— If retesting is performed by an excipient supplier and the results are used to extend the length of time that the material may be used, the date retested should also be reported on the COA. The specific tests that were subject to retesting should be clearly identified, and the results obtained upon retesting should be reported. After retesting, a new recommended re-evaluation date should be reported on the COA.

**Additional Dates**— Other dates may appear on a COA, if desired by the excipient supplier or requested by the user. Examples include the release date, shipping date, date of testing, and date the COA was printed or approved. Any additional dates that appear on a COA for excipients should include a clear indication of what the date represents or means.

#### TESTING FREQUENCY

For the excipients listed in the USP–NF, the product specifications are set by the supplier to include all parameters listed in the monograph. It is not required that analysis of all specification parameters be made on each lot (see General Notices and Requirements). However, sufficient analysis and process validation data should exist to ensure that the lot meets all specifications before it is released. This is an established practice that has been successfully used in industry for many years. Periodic testing of all parameters should be performed to revalidate the control system. The frequency of these periodic tests should be determined by the suppliers on the basis of their understanding of the manufacturing control system. At a minimum, the parameters should be checked once a year.

For excipients that are not included in USP–NF, specifications should be set by the supplier to ensure that the quality of the material is maintained on a continuing basis and reflects both the excipient manufacturing process and inherent properties. The analytical methods used to evaluate the characteristics of noncompendial excipients may be the same as those contained in the compendia, or may be unique to the supplier or the material. The methods should be demonstrated to provide accurate, reproducible, and consistent results for the characteristic being tested. It may be appropriate for noncompendial excipients to have some tests performed at reduced frequency.

The excipient user should evaluate the supplier's specifications and methods to ensure that they are appropriate and acceptable for the quality control needed for the manufacturing process of their drug product. The user should determine which of the supplier's specifications and methods are required for release of the excipient for use in their process. If additional tests or alternative methods are required by the user, appropriate specifications and methods, along with responsibility for performing the testing, must be agreed upon by the excipient supplier and user.

#### Reduced Frequency Testing

When analysis of some parameters is carried out at a reduced frequency (for example, every 10th lot), this should be clearly stated on the COA. Each specific test subject to reduced frequency testing should be indicated. Reduced frequency testing should be used only for excipients manufactured using a stable process. There should be a sound technical basis and sufficient documentation to support testing any parameter at a reduced frequency. This would normally include the following points:

- Appropriate validation of the manufacturing process
- Process control—attribute charting (when appropriate)
- GMP controls

As part of the justification for reduced testing, it is important that there be assurances in place showing that the manufacturer's process complies with appropriate excipient GMP requirements.

Some tests, because of their significance, should always be performed on each lot, whereas others may be candidates for reduced frequency testing. Attribute testing results in

qualitative data that provide pass/fail results or results expressed as less than or greater than a specified value. The result merely establishes compliance with a specification parameter. There are no data to indicate how well the material complies, as would be obtained from variable or quantitative test results.

Reduced frequency testing of an attribute requires that the manufacturer show that the qualitative parameter is in a state of statistical control. This necessitates tabulating the test results for consecutive lots produced.

**Skip-Lot Testing**— Skip-lot testing may be applied to an excipient that is made by either a batch or a continuous process. Various commonly accepted statistical sampling plans may be used to demonstrate appropriate process control. Examples of each are listed below.

**example 1:** For an average outgoing quality level (AOQL) of 1% and a test frequency of 1 in 10, the supplier should find 100 consecutive lots in conformance. At a 2% AOQL and a test frequency of 1 in 10, the supplier would test 50 consecutive lots. For a 1% AOQL and a 1 in 5 test frequency, the supplier would test 70 consecutive lots. Nomographs are available to determine the test requirements.

**example 2:** When the excipient is manufactured by a continuous process, no discrete lot is produced. The sampling plan again is based upon the risk of approving a lot that was nonconforming. By testing 140 consecutive lots before going to a test frequency of 1 in 10, the plan establishes a low risk of approving a lot that is noncompliant.

Once the requirement is met, the supplier can monitor conformance to the specification parameter by testing 1 in 10 lots. Should any lot fail the analysis, the supplier should return to 100% testing until the results once again meet the specification above.

Because excipients vary greatly in chemical and physical properties, the supplier of the excipient should determine which tests should be routinely performed and which tests may be appropriate for reduced frequency testing. This determination must be justified and documented on the basis of the adequacy of the supplier's control system. Documentation should be kept detailing the assumptions and the data supporting the skip-lot testing plan.

**Type A and Type B Tests**— Only certain types of tests are appropriate for reduced frequency testing. Type A is defined as tests that may not be easily controlled through standard process control techniques or that may change with time. These tests should normally be performed on each lot. Type B is defined as tests that normally can be controlled using standard process control techniques and that are not expected to change with time. These tests are candidates for reduced frequency testing. Examples of both types of tests are listed below.

**TYPE A: EXAMPLES OF TESTS THAT TYPICALLY NEED TO BE PERFORMED ON EVERY LOT**

- Identification—Required by GMPs for users (candidate for reduced frequency testing by suppliers)
  - Assay—Critical quality parameter (if specified)
  - Viscosity—Usually indicates grade
- Loss on drying (or moisture determination)—Indication of stability and appropriate process controls
  - Color—Indication of stability and appropriate process controls
  - pH—Indication of stability and appropriate process controls

**TYPE B: EXAMPLES OF TESTS THAT MAY BE CANDIDATES FOR REDUCED FREQUENCY TESTING**

- Manufacturing impurities—Based on starting materials and processes (e.g., Chloride, Sulfate, Nitrate, Glyoxal)
  - Heavy metals
    - Lead
    - Arsenic
  - Residue on ignition
  - Residual solvents

This is not meant to be an exhaustive list of tests. It simply provides some direction on how a supplier can assess the importance of each test to the overall control of the process. Tests listed as possible candidates for reduced frequency testing (Type B) may need to be routinely tested (Type A), depending on the raw materials and process. Determinations can also be made for some Type A tests to become Type B tests. In a dedicated facility, identification testing by the supplier may not be necessary.

**Documentation**— The supplier of an excipient should develop and maintain documentation that outlines the process control systems and validation data to justify the use of reduced frequency testing. This documentation should also include procedures for handling the impact of significant changes on the reduced frequency testing program.

The minimum number of lots to be fully tested for all specification parameters after a change has been made depends on the process and the significance of the change and should be based on sound statistical considerations.

Additionally, the documentation should contain procedures for re-evaluating the reduced frequency testing program when a testing failure occurs. Decisions regarding the continuance of reduced frequency testing should be justified on the basis of the reasons for the failure and the supplier's ability to provide assurances that the reduced frequency testing program or other in-process parameters would identify these types of failures in the future.

**Justifications for Reduced Frequency Testing**— The following are examples of situations where a sound technical basis can be demonstrated and where reduced frequency testing might therefore be justified. [note—There may be other such examples.]

- An impurity, by-product, or unreacted raw material could not be present in the product because the raw materials and chemical reactions used could not contain or generate such substances above the specified limits.
- The process capability index ( $C_p$ ) on the relevant parameter is high and based on a stable process. Statistical analysis of the reduced frequency data should show that the property remains stable and within specifications. A process is considered stable when the output of the process, regardless of the nature of the processing (batch or continuous), can be demonstrated by appropriate means to show a level of variability that consistently meets all aspects of the stated specification (both Pharmacopeia-specific and customer-specific) and is thus acceptable for its intended use. For continuous processing, it is also important to demonstrate that the material has been produced under conditions in which the process has achieved a form of "steady state", i.e., in which there is minimal operator intervention and in which the in-process parameters have been stabilized (see Appendix 2 for further definition of this concept and for determining levels of control).
- For a continuous process, the in-process analyses show that the property that is determined at reduced frequency is stable and within specification. Repeating the test on each lot would be redundant.
- An analysis that is determined on every lot has been shown to strongly correlate with an analysis that is run at a reduced frequency. The correlation shows that if a lot is within specification on the first analysis, it will be within specification on the second analysis.

#### USE OF ELECTRONIC SIGNATURES

Because of the growing dependence on computers and the need to accommodate paperless record systems, an electronic alternative to handwritten records and signatures is suggested. Excipient suppliers have added computer information systems to enhance productivity.

The primary issue with transfer of a COA without a handwritten signature is the validation of data. There are several considerations that should be met before an electronic signature or name attachment to a COA is considered acceptable.

- Computer systems access must be limited to authorized individuals: access is gained only after inputting a user name and a password. The system should require frequent changes of each individual password.
  - A confirmation of the integrity and accuracy of the information stored in the system should be completed.
- The operation of the system must be checked routinely to ensure that the correct information is transferred from the database to the printed record.
  - Data entered into a database from which information is extracted for a COA should be accompanied by time- and date-stamped audit trails.

When these criteria are met, the issuance of COAs with electronic signatures or the responsible person's name attached to the document, in lieu of a handwritten signature, is acceptable. [note—Computer systems are currently regulated by 21 CFR 11 of the FDA. Users should monitor the FDA's approach to compliance in this area.]

## DISTRIBUTOR INFORMATION

The presentation of a COA issued by a distributor presents some challenges. Because COAs are important documents characterizing the excipients and the state of their quality, the source of that information becomes very important to the end user(s). Because distributors take on different roles in fulfilling the services for which they are contracted, it is necessary to ensure that procedures and methods are appropriate for the functions performed.

Distributors may function in a number of different capacities relating to the movement of excipients and to services associated with their production. Some are simply pass-through locations in which nothing is done to the excipient with the exception of storage and handling. Others serve as extensions of the manufacturer's process by taking bulk quantities and repackaging them for the manufacturer. Still others purchase excipients and repackage them under a different label for sale and distribution. These scenarios should be understood and properly documented with programs that will protect the integrity and safety of the excipients as they move through the distribution process.

**Original Manufacturer and Manufacturing Site**— The identity of the original manufacturer and the manufacturing site should be included on the COA for excipients. This information is important because it provides traceability for specific excipient lots and assures the excipient users that they are consistently obtaining material from the same manufacturer and site.

Reporting the identity and location of the manufacturer does not represent an issue when the original manufacturer is also the direct supplier of the excipient to the pharmaceutical customers. However, it is recognized that this information may be considered proprietary by an excipient distributor. To adequately address this issue, excipient distributors should either list the specific information identifying the original manufacturer and location or provide the information by reporting an appropriate code, which is assigned in order to unambiguously identify the original manufacturer and manufacturing site. To protect the secrecy of this information, the meaning of the code does not have to be revealed to intermediary distributors.

**Certificate of Analysis Data**— When a distributor is primarily used as a pass-through of the excipient without any changes to the excipient and packaging, the COA that accompanies the excipient from the manufacturer can be passed on in the original form. If the data are extracted, translated, or rewritten on other letterhead, a system should be in place to check the rewritten information, and justification should be demonstrated upon request. Alternatively, the source of the data should be indicated on the document.

For a distributor that takes bulk quantities of an excipient from a manufacturer and introduces the bulk quantities into a process (e.g., conveyance and storage system), analysis of the packaged excipient should be performed to demonstrate the same quality as the lot (batch) introduced. Appropriate analytical data should be included on the COA to verify the quality.

The distributor should use equivalent methodology and equipment for the analytical evaluation. Some data may be used from the original manufacturer's COA with appropriate justification.

In all scenarios, it is expected that the distributor will have the appropriate level of GMP in place.

## APPENDIX 1

## DEFINITIONS

**Acceptance Criteria**— The specifications and acceptance or rejection limits—such as acceptable quality level or unacceptable quality level with an associated sampling plan—that are necessary for making a decision to accept or reject a lot or batch of raw material, intermediate, packaging material, or excipient.

**Batch (or Lot)**— A defined quantity of excipient processed so that it could be expected to be homogeneous. In a continuous process, a batch corresponds to a defined portion of the production, based on time or quantity (e.g., vessel's volume, 1 day's production, etc.).

**Batch Number (or Lot Number)**— A unique and distinctive combination of numbers and/or letters from which the complete history of the manufacture, processing, packaging, coding, and distribution of a batch can be determined.

**Batch Process**— A manufacturing process that produces the excipient from a discrete supply of raw materials that is present before the completion of the reaction.

**Certificate of Analysis (COA)**— A document relating specifically to the results of testing a representative sample drawn from the batch of material to be delivered.

**Chemical Property**— A quality parameter that is measured by chemical or physicochemical test methods.

**Continuous Process**— A manufacturing process that continually produces the excipient from a continuous supply of raw material.

**Contract Facility**— An internal or external facility that provides services to the manufacturer or distributor of an excipient. These can include, but are not limited to, the following: manufacturing facilities, laboratories, repackaging facilities (including labeling), and warehouses.

**Date of Manufacture**— A date indicating the completion of the final manufacturing process (as defined by the supplier for the particular excipient and process).

**Date Retested**— The date when retesting is performed by an excipient supplier to extend the length of time that the material may be used.

**Distributor**— A party other than the manufacturer who sells the excipient.

**Excipient**— Any substance, other than the active pharmaceutical ingredient or drug product, that has been appropriately evaluated for safety and is included in a drug delivery system to aid the processing of the drug delivery system during manufacture; to protect, support, or enhance stability, bioavailability, or patient acceptability; to assist in product identification; or to enhance any other attribute of the overall safety and effectiveness of the drug delivery system during storage or use.

**Expiration Date**— The date after which the supplier recommends that the material should not be used.

**Impurity**— Any component of an excipient that is not the intended chemical entity but is present as a consequence of either the raw materials used or the manufacturing process.

**Lot**— See Batch.

**Lot Number**— See Batch Number.

**Manufacturer**— A party who performs the final processing step.

**Packaging**— The container and its components that hold the excipient for storage and transport to the customer.

**Periodic Testing Program**— See Skip-Lot Testing Program.

**Physical Property**— A quality parameter that can be measured solely with mechanical equipment.

**Process**— The set of operating instructions describing how the excipient is to be synthesized, isolated, purified, etc.

**Process Capability Index (Cp)**— A statistical measurement that can be used to assess whether the process is adequate to meet specifications. A state of statistical control can be said to exist if the random variation in test results for a process parameter is such that the calculated process capability is greater than 1.33 (see Appendix 2 for further definition).

**Process Step**— An instruction to the excipient manufacturing personnel directing that an operation be performed.

**Recommended Re-Evaluation Date**— The date suggested by the supplier when the material should be re-evaluated to ensure continued compliance with specifications. Differs from the Expiration Date in that the excipient may be re-evaluated to extend the length of time the material may be used, if supported by the results of the evaluation and appropriate stability data.

**Reduced Frequency Testing Program**— See Skip-Lot Testing.

**Repackaging**— Transfer of an excipient from one container to another.

**Reprocessing**— Introducing previously processed material that did not conform to standards or specifications back into the process and repeating steps that are already part of the normal manufacturing process.

Significant Change— Any change that alters an excipient's physical or chemical property from the norm or that is likely to alter the excipient's performance in the dosage form.

Site— A location where the excipient is manufactured. This may be within the facility but in a different operational area, or at a remote facility, including a contract manufacturer.

Skip-Lot Testing Program— Periodic or intermittent testing performed for a particular test parameter that is justified by historical data demonstrating a state of statistical process control.

Specification— The quality parameters to which the excipient, component, or intermediate must conform and that serve as a basis for quality evaluation.

Stable Process— A process whose output, regardless of the nature of the processing (batch or continuous), can be demonstrated by appropriate means to show a level of variability that consistently meets all aspects of the stated specification (both USP-specific and customer-specific) and is thus acceptable for its intended use.

Supplier— A manufacturer or distributor who directly provides the excipient to the user.

User— A party who uses an excipient in the manufacture of a drug product or another excipient.

## APPENDIX 2

### STATE OF STATISTICAL CONTROL: PROCESS CAPABILITY PARAMETERS FOR DETERMINING LEVELS OF CONTROL

A process is considered to be in a state of statistical control if variations among the observed sampling results from the process can be attributed to a constant system of chance causes. Process capability index ( $C_p$ ) or capability index adjusted for the process average ( $C_{pk}$ ) or performance index ( $P_p$ ) or performance index adjusted for the process average

( $P_{pk}$ ) can be used to assess whether the process is adequate to meet specifications. Values of these parameters exceeding 1.33 show that the process is adequate to meet specifications. Values between 1.00 and 1.33 indicate that the process, although adequate to meet specifications, will require close control. Values below 1.00 indicate that the process is not adequate to meet specifications and that the process and/or specifications should be changed.  $P_p/P_{pk}$  will always be less than or equal to  $C_p/C_{pk}$ , respectively. The essential

difference between the capability and the performance indices is the data used. Capability indices require the calculation of  $\sigma$ , the population standard deviation, whereas the performance indices require the calculation of  $s$ , the sample standard deviation. Thus for pharmaceutical excipients a state of statistical control can be said to exist if the random variation in test results for a process parameter is such that the calculated process capability index or performance index is greater than 1.33.

### 1081 GEL STRENGTH OF GELATIN

Pipet 105 mL of water at  $10^{\circ}$  to  $15^{\circ}$  into a standard Bloom bottle, add 7.5 g of Gelatin, and stir. Allow to stand for 1 hour, then bring to a temperature of  $62^{\circ}$  in 15 minutes by placing in a water bath regulated at  $65^{\circ}$  (the substance may be swirled several times to aid solution). Finally mix by inversion, allow to stand for 15 minutes, and place in a water bath at  $10 \pm 0.1^{\circ}$ . Chill, without disturbance, for 17 hours. Determine the gel strength in a Bloom Gelometer (a device developed to make this determination under standardized conditions) adjusted for 4-mm depression and to deliver  $200 \pm 5$  g of shot per 5 seconds, using the 12.7-mm diameter (nonbeveled) plunger.

### 1086 IMPURITIES IN OFFICIAL ARTICLES

#### INTRODUCTION

This general information chapter covers impurities or degradation products in drug substances and degradation products in drug products. Impurities or degradation products in drug substances can arise during the manufacturing process or during storage of the drug substance. The degradation products in drug products can arise from drug substances or reaction products of the drug substance with an excipient or an immediate container–closure system. Biological, biotechnological, and radiopharmaceutical products are not covered in this chapter.

Concepts about purity change with time and are inseparable from developments in analytical chemistry. If a material previously considered to be pure can be resolved into more than one component, that material can be redefined into new terms of purity and impurity. Inorganic, organic, biochemical, isomeric, or polymeric components can all be considered impurities. Microbiological species or strains are sometimes described in similar terms of resolving into more than one component.

Communications about impurities or degradation products in compendial articles may be improved by including in this Pharmacopeia the definitions of terms and the contexts in which these terms are used. (See Definitions below.) There has been much activity and discussion in recent years about term definition. Certain industry-wide concerns about terminology and context deserve widespread publication and ready retrievability and are included here. See Foreign Substances and Impurities in the section Tests and Assays under General Notices and Requirements, as well as the general chapter [Ordinary Impurities](#) (466). Some other general chapters added over the years have also addressed topics of purity or impurity as these have come into focus or as analytical methodology has become available. Analytical aspects are enlarged upon in the chapter [Validation of Compendial Procedures](#) (1225).

Monographs for drug substances usually cite one of three types of purity tests: (1) a chromatographic purity test coupled with a nonspecific assay; (2) a chromatographic purity-indicating method that serves as the assay; or (3) a specific test and limit for a known impurity, an approach that usually requires a Reference Standard for that impurity. Modern separation methods clearly play a dominant role in scientific research today because these methods simultaneously separate and measure components and fulfill the analytical ideal of making measurements only on purified specimens. Nevertheless, the more classical methods based on titrimetry, colorimetry, spectrophotometry, single or multiple partitions, or changes in physical constants (or any other tests or assays) lose none of their previous validities. The purity profile of a specimen that is constructed from the results of experiments using a number of analytical methods is the ultimate goal.

Purity or impurity measurements for drug products present a challenge to Pharmacopeial standards-setting. Where degradation of a drug product over time is at issue, the same analytical methods that are stability-indicating are also purity-indicating. Resolution of the active ingredient(s) from the excipients necessary to the preparation presents the same qualitative problem. Thus, many monographs for Pharmacopeial preparations feature chromatographic assays. Where more significant impurities are known, some monographs set forth specific limit tests. In general, however, this Pharmacopeia does not repeat impurity tests in subsequent preparations where these appear in the monographs of drug substances and where these impurities are not expected to increase. It is presumed that adequate retention specimens are in storage for the exact batch of drug substances used in any specific lot of a drug product. Whenever analysis of an official article raises a question of the official attributes of any of the drug substances used, subsequent analysis of retention specimens is in order.

Pharmaceutical manufacturers interact with regulatory agencies in developing new drug substances and new drug products, and cooperate with the compendia in writing official monographs for the compendial articles the manufacturers produce. Establishment of impurity limits in drug substances and drug products should proceed on a rational basis so that everyone involved in the development and approval phases can carry on their work in a predictable manner. Although drug development in the United States is the primary focus of this section of the chapter, the subject also has broad applicability across national boundaries.

Manufacturers share with regulatory agencies and with the compendia the goal of making available to the public high-quality products that are both safe and efficacious. This goal continues to be achieved through rational approaches to the complex process of drug development. Tests used at all stages of drug development and marketing should not be interpreted individually but as a whole. Controls on raw materials and on manufacturing as well as those on drug substances, along with toxicological and clinical studies performed, ensure the safety and efficacy of drug products. It is more rational to identify impurities or degradation products and to set limits based on the factors detailed here, relying on the scientific judgments of manufacturers, the compendia, and regulators to arrive at sets of acceptable limits for identified and unidentified impurities or degradation products.

Limits are set for impurity levels or degradation products as one of the steps in ensuring the identity, strength, quality, and chemical purity of drug substances or drug products. The ultimate goal is to produce a final drug product of high quality that is safe and efficacious and remains so throughout its shelf life. The setting of limits for impurities or degradation products in drug substances is a complex process that considers a number of factors:

1. the toxicology of a drug substance containing typical levels of impurities and/or the toxicology of impurities relative to a drug substance;
2. the route of administration, e.g., oral, topical, parenteral, or intrathecal;
3. the daily dose, i.e., frequency and amount (micrograms or grams) administered of a drug substance;
4. the target population (age and disease state), e.g., neonates, children, or senior citizens;
5. the pharmacology of an impurity, when appropriate;
6. the source of a drug substance, e.g., synthetic, natural product, or biotechnology;
7. the duration of therapy, i.e., administration over a long period (treatment of chronic conditions) versus administration intended for a short duration (treatment of acute conditions); and
8. the capability of a manufacturer to produce consistently high-quality material.

Concepts for setting impurity or degradation product limits in drug substances are based on chemistry and safety concerns. As such, limits for organic and inorganic impurities and residual solvents should be established for drug substances. The basic tenet for setting limits is that levels of impurities or degradation products in a drug substance must be controlled to ensure its safety and quality throughout its development to use in a drug product.

For drug products the concept for setting degradation product limits is based on sound scientific judgment as applied to available data on the safety and stability of the drug product, which may include the degradation pathways of the drug substance, the manufacturing process, known excipient interactions, any safety assessment studies, stability studies conducted under the recommended storage conditions, and ancillary studies that may provide additional information on the stability profile of the drug product. A rationale should be provided for exclusion of those impurities that are not degradation products (e.g., process impurities from drug substance and impurities arising from excipients).

For drug substances and drug products, limits are appropriately set no higher than the level that can be justified (e.g., safety data, literature references, etc.) and no lower than the level achievable by the manufacturing process and analytical capability. Where there is no safety concern, limits should be based on (a) data generated on actual batches of the drug substance or drug product, allowing sufficient latitude to deal with normal process and analytical variation, and (b) stability characteristics.

Documented evidence that the analytical procedure used to evaluate impurities or degradation products is validated and suitable for the detection and quantification of impurities or degradation products should be established.

The setting of limits on impurities or degradation products is an evolutionary process, beginning in the United States before an investigational new drug (IND) is filed and continuing until well after the approval of a new drug application (NDA). Therefore, it is appropriate to address different stages in drug development as separate issues. There are three points in the drug development process where the setting of limits may be significantly different: (1) at the initial IND application, (2) at the filing of the NDA, and (3) after NDA approval. The filing of an abbreviated new drug application (ANDA) is another activity in which limits are set on impurities or degradation products. Since the approach may vary from that of filing an NDA, it is addressed as a separate issue. The underlying assumption is that the analytical methods used to evaluate impurities or degradation products are suitable for their intended purpose at each stage in the development.

#### INITIAL IND FILING

**Drug Substances**— At the initial IND filing, the chemical nature of a drug substance has generally been defined. The manufacturing process normally is in an early stage of development, and materials may be produced on a laboratory scale. Usually few batches have been made and, therefore, little historical data is available. The reference materials of a drug substance may be relatively impure. Limits for the purity of a drug substance are set to indicate drug quality. The setting of limits on related substances and process contaminants can be characterized as follows.

1. Limits are set on total impurities, and an upper limit may be set on any single impurity. The limit for total impurities should maintain, if possible, a nominal composition material balance.
2. Impurity profiles are documented. These are profiles of the lots of drug substances used in clinical studies and in toxicological studies that establish the safety of drug substances. The lots used in these studies should be typical products of the manufacturing process in use at that time.
3. Limits for residual solvents are based on the known toxicology of the solvents and on the manufacturing capabilities and dosing regimens.
4. General inorganic impurities are monitored by appropriate tests such as a heavy metals limit test and/or a test for residue on ignition. Traditional compendial limits are applied unless otherwise indicated. Specific residual metals that appear during manufacturing should be monitored by appropriate analytical techniques, and limits should be set based on the toxicological properties of these metals.
5. Appropriate limits are set for impurities known to be toxic.
6. If appropriate, enantiomeric purity is controlled.

Although water is not classified as an impurity, limits for water content may be needed to ensure the stability or ease of processing a drug substance.

**Drug Product**— At the initial IND filing, the dosage form of a drug product has been identified, which is appropriate for early clinical studies (and may or may not be representative of the drug product that will eventually be marketed). Usually, few batches have been made and, therefore, little historical data is available.

1. Qualitative and quantitative limits on degradation products may not be established at this point due to the limited data available. Typically, degradation products will be monitored as part of the stability evaluation of the drug product.
2. Dating for use of a drug product in clinical studies will be based on data from ongoing stability studies. If the data indicate the presence of degradation products, dating and storage conditions are controlled to ensure any degradation products are controlled within industry accepted limits or within limits established through safety assessment studies.
3. Limits for residual solvents, if appropriate, are based on the known toxicology of the solvents and on the manufacturing capabilities and dosing regimens. When amendments to the IND are filed, limits for impurities in drug substance and degradation products in drug substance or drug product may be updated based on additional data as they become available.

#### NDA FILING

**Drug Substances**— During the IND phases of drug development, the manufacturing process for a drug substance may undergo a number of revisions. Generally, the scale will have changed from laboratory size and will approach or reach full production batch size. A number of batches will normally have been produced, and a historical data base of the results of testing for impurities will exist. When significant changes in a manufacturing process are made, the impurity profile should be reviewed to determine if the toxicological studies are still supportive.

At the NDA stage a reference standard of defined purity is available, analytical methods have been validated, impurity and degradation profiles are known, and enantiomeric purity has

been evaluated. The setting of limits on related substances and process contaminants can be characterized as follows.

1. Consistency of the impurity profile of a drug substance has been established.
2. IND limits for total and individual impurities (identified and unidentified) are reviewed and adjusted based on manufacturing experience and toxicological data.
3. Impurities present in significant amounts are identified and individual limits are set. However, it is not always possible to identify or prepare authentic substances for impurities. The labile nature of some impurities precludes this possibility. Limits may be set on these substances based on comparison of lots produced and used in toxicological and clinical studies.
4. The impurity profiles of the lots designated for marketing should not be significantly higher than those of the lot(s) used for toxicological and clinical studies.
5. The composition material balance should be used, if possible, to evaluate the adequacy of the controls.
6. Limits for residual solvents are based on the known toxicology of the solvents and on the manufacturing capabilities and dosing regimens.
7. Limits are set for inorganic impurities by appropriate tests such as a heavy metals limit test and/or by a test for residue on ignition. Traditional compendial limits are applied unless otherwise indicated. Based on toxicological properties, limits may be set for specific residual metals that appear during manufacturing.
8. Additional guidance for setting limits can be found in various ICH and FDA guidance documents.

Drug Product— Similarly, for the drug product, the dosage form may change, the number or scale of batches may increase, and more stability data will have become available. Methods will have been validated. The setting of limits can be characterized as follows:

1. IND limits for total and individual degradation products (identified and unidentified) are reviewed and adjusted based on manufacturing experience, stability data, and toxicological data.
2. Degradation products present in significant amounts are identified and individual limits are set. However, it is not always possible to identify or prepare authentic substances for degradation products.
3. The degradation product profiles of the lots designated for marketing should not be significantly higher than those of the lot(s) used for toxicological and clinical studies.
4. The mass balance should be used, if possible, to evaluate the adequacy of the controls.
5. Limits for residual solvents, if appropriate, are based on the known toxicology of the solvents and on the manufacturing capabilities and dosing regimens.
6. Additional guidance for setting limits can be found in various ICH and FDA guidance documents.

#### POST NDA APPROVAL

After approval and marketing of a pharmaceutical product, significant changes may be made in manufacturing the drug substance. There may be technological, ecological, economic, or safety reasons for these changes. If they occur, the Pharmacopeial and NDA impurity and degradation product limits and rationale should be reviewed; the limits should be revised when indicated to ensure similar or improved quality of the drug substance or drug product.

#### ANDA FILING

The drug substance for a pharmaceutical product eligible for ANDA status is frequently an official article and should be well characterized analytically. Drug substances are typically available from multiple sources, and each source may have a different manufacturing process. Therefore, it is essential that the dosage form manufacturer evaluate each supplier's drug substance impurity or degradation profiles. Limits can then be set based on the more detailed concepts described for NDA filing, including review of compendial monographs for appropriateness.

#### DEFINITIONS

**Concomitant Components**— Concomitant components are characteristic of many drug substances and are not considered to be impurities in the Pharmacopeial sense. Limits on contents, or specified ranges, or defined mixtures are set forth for concomitant components in this Pharmacopeia. Examples of concomitant components are geometric and optical isomers (or racemates) and antibiotics that are mixtures. Any component that can be considered a toxic impurity because of significant undesirable biological effect is not considered to be a concomitant component.

**Foreign Substances (Extraneous Contaminants)**— Foreign substances (extraneous contaminants), which are introduced by contamination or adulteration, are not consequences of the synthesis or preparation of compendial articles and thus cannot be anticipated when monograph tests and assays are selected. The presence of objectionable foreign substances not revealed by monograph tests and assays constitutes a variance from the official standard. Examples of foreign substances include ephedrine in Ipecac or a pesticide in an oral liquid analgesic. Allowance is made in this Pharmacopeia for the detection of foreign substances by unofficial methods. (See Foreign Substances and Impurities in the section Tests and Assays under General Notices and Requirements.)

**Identified Impurities and Identified Degradation Products**— Impurities or degradation products for which structural characterizations have been achieved.

**Inorganic Impurities**— Inorganic impurities can result from the manufacturing process (e.g., residual metals, inorganic salts, filter aids, etc.). Inorganic impurities are typically controlled by tests such as [Heavy Metals](#) (231) and [Residue on Ignition](#) (281). Information found in [Plasma Spectrochemistry](#) (730) and [Ion Chromatography](#) (1065) may also be of value.

**Ordinary Impurities**— Some monographs make reference to ordinary impurities. For more details see [Ordinary Impurities](#) (466).

**Process Contaminants**— Process contaminants are identified or unidentified substances (excluding related substances and water), including reagents, catalysts, other inorganic impurities (e.g., heavy metals, chloride, or sulfate); and may also include foreign substances (extraneous contaminants). These contaminants may be introduced during manufacturing or handling procedures.

**Related Substances**— Related substances are structurally related to a drug substance. These substances may be (a) identified or unidentified impurities arising from synthesis manufacturing process such as intermediates or by-products and do not increase on storage or (b) identified or unidentified degradation products that result from drug substance or drug product manufacturing processes or arise during storage of a material.

**Residual Solvents**— Refer to [Residual Solvents](#) (467).

**Specified Impurities and Specified Degradation Products**— Previously referred to as Signal Impurities, specified impurities or specified degradation products are impurities or degradation products that are individually listed and limited with specific acceptance criteria in individual monographs as applicable. Specified impurities or specified degradation products can be identified or unidentified.

**Toxic Impurities**— Toxic impurities have significant undesirable biological activity, even as minor components, and require individual identification and quantification by specific tests. These impurities may arise out of the synthesis, preparation, or degradation of compendial articles. Based on validation data, individualized tests and specifications are selected. These feature comparison to a Reference Standard of the impurity, if available. It is incumbent on the manufacturer to provide data that would support the classification of such impurities as toxic impurities.

**Unidentified Impurities and Unidentified Degradation Products**— Impurities or degradation products for which structural characterizations have not been achieved and that are identified solely by qualitative analytical properties (e.g., chromatographic retention times).

**Unspecified Impurities and Unspecified Degradation Products**— Impurities or degradation products that are limited by general acceptance criteria but not individually listed with their own specific acceptance criteria in individual monographs.

**1087 APPARENT INTRINSIC DISSOLUTION—DISSOLUTION TESTING PROCEDURES FOR ROTATING DISK AND STATIONARY DISK**

This general information chapter [Apparent Intrinsic Dissolution—Dissolution Testing Procedures for Rotating Disk and Stationary Disk](#) **1087** discusses the determination of dissolution rates from nondisintegrating compacts exposing a fixed surface area to a given solvent medium. Compact, as used here, is a nondisintegrating mass resulting from compression of the material under test using appropriate pressure conditions. A single surface having specified physical dimensions is presented for dissolution. Determination of the rate of dissolution can be important during the course of the development of new chemical entities because it sometimes permits prediction of potential bioavailability problems and may also be useful to characterize compendial articles such as excipients or drug substances. Intrinsic dissolution studies are characterization studies and are not referenced in individual monographs. Information provided in this general information chapter is intended to be adapted via a specific protocol appropriate to a specified material.

Dissolution rate generally is expressed as the mass of solute appearing in the dissolution medium per unit time (e.g., mass sec<sup>-1</sup>), but dissolution flux is expressed as the rate per unit area (e.g., mass cm<sup>-2</sup> sec<sup>-1</sup>). Reporting dissolution flux is preferred because it is normalized for surface area, and for a pure drug substance is commonly called intrinsic dissolution rate. Dissolution rate is influenced by intrinsic solid-state properties such as crystalline state, including polymorphs and solvates, as well as degree of noncrystallinity. Numerous procedures are available for modifying the physicochemical properties of chemical entities so that their solubility and dissolution properties are enhanced. Among these are coprecipitates and the use of racemates and enantiomeric mixtures. The effect of impurities associated with a material can also significantly alter its dissolution properties. Dissolution properties are also influenced by extrinsic factors such as surface area, hydrodynamics, and dissolution medium properties, including solvent (typically water), presence of surfactants, temperature, fluid viscosity, pH, buffer type, and buffer strength.

Rotating disk and stationary disk dissolution procedures are sufficiently versatile to allow the study of characteristics of compounds of pharmaceutical interest under a variety of test conditions. Characteristics common to both apparatuses include the following:

1. They are adaptable to use with standard dissolution testing stations, and both use a tablet die to hold the nondisintegrating compact during the dissolution test.
2. They rely on compression of the test compound into a compact that does not flake or fall free during the dissolution test.
3. A single surface of known geometry and physical dimension is presented for dissolution.
4. The die is located at a fixed position in the vessel, which decreases the variation of hydrodynamic conditions.

A difference between the two procedures is the source of fluid flow over the dissolving surface. In the case of the rotating disk procedure, fluid flow is generated by the rotation of the die in a quiescent fluid, but fluid flow is generated by a paddle or other stirring device for the stationary disk procedure.

#### EXPERIMENTAL PROCEDURE

The procedure for carrying out dissolution studies with the two types of apparatus consists of preparing a nondisintegrating compact of material using a suitable compaction device, placing the compact and surrounding die assembly in a suitable dissolution medium, subjecting the compact to the desired hydrodynamics near the compact surface, and measuring the amount of dissolved solute as a function of time.

Compacts are typically prepared using an apparatus that consists of a die, an upper punch, and a lower surface plate fabricated out of hardened steel or other material that allows the compression of material into a nondisintegrating compact. An alternative compaction apparatus consists of a die and two punches. Other configurations that achieve a nondisintegrating compact of constant surface area also may be used. The nondisintegrating compact typically has a diameter of 0.2 cm to 1.5 cm.

##### Compact Preparation

Attach the smooth lower surface plate to the underside of the die, or alternatively, insert the lower punch using an appropriate clamping system. Accurately weigh a quantity of material necessary to achieve an acceptable compact and transfer to the die cavity. Place the upper punch into the die cavity, and compress the powder on a hydraulic press at a compression pressure required to form a nondisintegrating compact that will remain in the die assembly for the length of the test. Compression for 1 minute at 15 MPa usually is sufficient for many organic crystalline compounds, but alternative compression conditions that avoid the formation of capillaries should be evaluated. For a given substance, the compact preparation, once optimized is standardized to facilitate comparison of different samples of the substance.

Changes in crystalline form may occur during compression; therefore, confirmation of solid state form should be performed by powder X-ray diffraction or other similar technique. Remove the surface plate or lower punch. Remove loose powder from the surface of the compact and die by blowing compressed air or nitrogen over the surface.

##### Dissolution Medium

The choice of dissolution medium is an important consideration. Whenever possible, testing should be performed under sink conditions to avoid artificially retarding the dissolution rate due to approach of solute saturation of the medium. Dissolution measurements are typically made in aqueous media. To approximate in vivo conditions, measurements may be run in the physiological pH range at 37°. The procedure when possible is carried out under the same conditions that are used to determine the intrinsic solubility of the solid state form being tested. Dissolution media should be deaerated immediately prior to use to avoid air bubbles forming on the compact or die surface.<sup>1</sup>

The medium temperature and pH must be controlled, especially when dealing with ionizable compounds and salts. In the latter cases, the dissolution rate may depend strongly on the pH, buffer species, and buffer concentration. A simplifying assumption in constant surface area dissolution testing is that the pH at the surface of the dissolving compact is the same as the pH of the bulk dissolution medium. For nonionizable compounds, this is relatively simple because no significant pH dependence on dissolution rate is expected. For acids and bases, the solute can alter the pH at and near the surface of the compact as it dissolves. Under these conditions, the pH at the surface of the compact may be quite different from the bulk pH due to the self-buffering capacity of the solute. To assess intrinsic solubility, experimental conditions should be chosen to eliminate the effect of solute buffering, alteration of solution pH, and precipitation of other solid state forms at the surface of the compact. For weak acids, the pH of the dissolution medium should be one to two pH units below the pKa of the dissolving species. For weak bases, the pH of the dissolution medium should be one to two pH units above the pKa of the dissolving species.

##### Apparatus

Rotating Disk—A typical apparatus ([Figure 1](#)) consists of a punch and die fabricated out of hardened steel. The base of the die has three threaded holes for the attachment of a surface plate made of polished steel, providing a mirror-smooth base for the compacted pellet. The die has a cavity into which is placed a measured amount of the material whose intrinsic dissolution rate is to be determined. The punch is then inserted in the die cavity and the test material is compressed with a hydraulic press. [note—A hole through the head of the punch allows insertion of a metal rod to facilitate removal from the die after the test.] A compacted pellet of the material is formed in the cavity with a single face of defined area exposed on the bottom of the die.

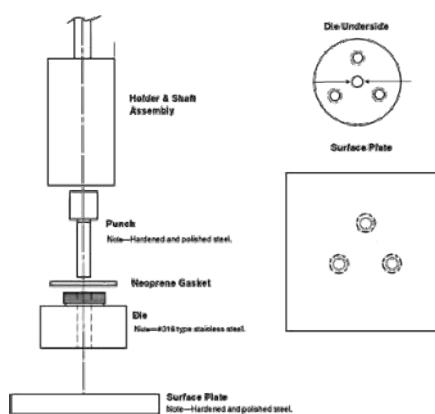

Figure 1

The die assembly is then attached to a shaft constructed of an appropriate material (typically steel). The shaft holding the die assembly is positioned so that when the die assembly is lowered into the dissolution medium (Figure 2) the exposed surface of the compact will be not less than 1.0 cm from the bottom of the vessel and nominally in a horizontal position. The die assembly should be aligned to minimize wobble, and air bubbles should not be allowed to form on the compact or die surface.

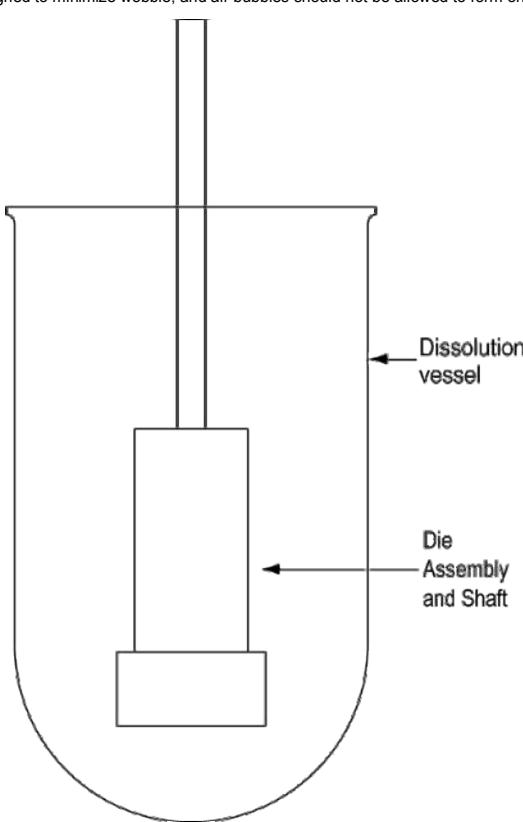

Figure 2

A rotating disk speed of 300 rpm is recommended. Typical rotation speeds may range from 60 rpm to 500 rpm. The dissolution rate depends on the rotation speed used. This parameter should be selected in order to admit at least five sample points during the test, but excessive stirring speeds may create shear patterns on the surface of the dissolving material that could cause aberrant results (i.e., nonlinearity). Typically, the concentration of the test specimen is measured as a function of time, and the amount dissolved is then calculated. The sampling interval will be determined by the speed of the dissolution process. If samples are removed from the dissolution medium, the cumulative amount dissolved at each time point should be corrected for losses due to sampling.

**Stationary Disk**— The apparatus (Figure 3) consists of a steel punch, die, and a base plate. The die base has three holes for the attachment of the base plate. The three fixed screws on the base plate are inserted through the three holes on the die and then fastened with three washers and nuts. The test material is placed into the die cavity. The punch is then inserted into the cavity and compressed, with the aid of a bench top press. The base plate is then disconnected from the die to expose a smooth compact pellet surface. A gasket is placed around the threaded shoulder of the die and a polypropylene cap is then screwed onto the threaded shoulder of the die.

The die assembly is then positioned at the bottom of a specially designed dissolution vessel with a flat bottom (Figure 4). The stirring unit (e.g., paddle) is positioned at an appropriate distance (typically 2.54 cm) from the compact surface. The die assembly and stirring unit should be aligned to ensure consistent hydrodynamics, and air bubbles should not be present on the compact surface during testing. Alternative configurations may be utilized if adequate characterization and control of the hydrodynamics can be established.

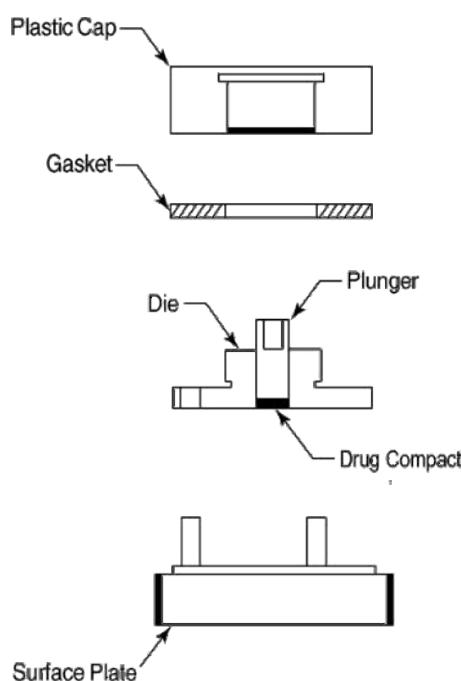

Figure 3

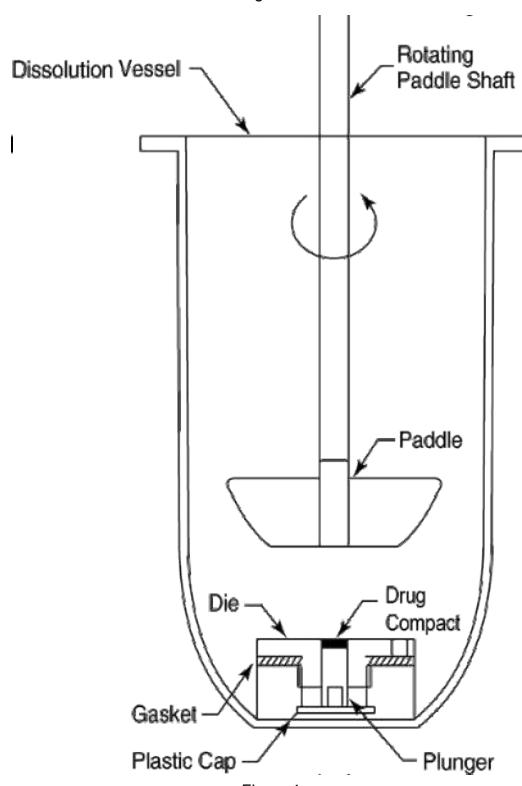

Figure 4

The dissolution rate depends on the rotation speed and precise hydrodynamics that exist. Typically, the concentration of the test specimen is measured as a function of time, and the amount dissolved is then calculated. The sampling interval will be determined by the speed of the dissolution process (see Rotating Disk). If samples are removed from the dissolution medium, the cumulative amount dissolved at each time point should be corrected for losses due to sampling.

#### DATA ANALYSIS AND INTERPRETATION

The dissolution rate is determined by plotting the cumulative amount of solute dissolved against time. Linear regression analysis is performed on data points in the initial linear region of the dissolution curve. The slope corresponds to the dissolution rate (mass sec<sup>-1</sup>). (More precise estimates of slope can be obtained using a generalized linear model that takes into account correlations among the measurements of the cumulative amounts dissolved at the various sampling times.)

The amount versus time profiles may show curvature. When this occurs, only the initial linear portion of the profile is used to determine the dissolution rate. Upward curvature (positive second derivative) of the concentration versus time data is typically indicative of a systematic experimental problem. Possible problems include physical degradation of the compact by cracking, delaminating, or disintegration. Downward (negative second derivative) curvature of the dissolution profile is often indicative of a transformation of the solid form of the compact at the surface or when saturation of the dissolution medium is inadvertently being approached. This often occurs when a less thermodynamically stable crystalline form converts to a more stable form. Examples include conversion from an amorphous form to a crystalline form or from an anhydrous form to a hydrate form, or the formation of a salt or a salt converting to the corresponding free acid or free base. If such curvature is observed, the crystalline form of the compact may be assessed by removing it from the medium and examining it by powder X-ray diffraction or another similar technique to determine if the exposed surface area is changing.

The constant surface area dissolution rate is reported in units of mass sec<sup>-1</sup>, and the dissolution flux is reported in units of mass cm<sup>-2</sup> sec<sup>-1</sup>. The dissolution flux is calculated by

...ding the dissolution rate by the surface area of the compact. Test conditions, typically a description of the apparatus, rotation speed, temperature, buffer species and strength, pH, and ionic strength should also be reported with the analyses.

- 1 One method of deaeration is as follows: Heat the medium, while stirring gently, to about 41°, immediately filter under vacuum using a filter having a porosity of 0.45 µm or less, with vigorous stirring, and continue stirring under vacuum for about 5 minutes. Other deaeration techniques for removal of dissolved gases may be used.

#### 1088 IN VITRO AND IN VIVO EVALUATION OF DOSAGE FORMS

The Pharmacopeia provides for dissolution and drug release testing in the majority of monographs for solid oral and transdermal dosage forms. In recognition of the sensitivity of dissolution tests, where a valid bioavailability-bioequivalence (BA-BE) study is in hand, the policy of this Pharmacopeia has been to give this information dominant consideration in setting dissolution standards. Early practice was to develop dissolution requirements based on the in vitro performance of clinically successful formulations. Similarity in dissolution behavior has long been sought from the perspectives of both bioavailability and quality control considerations.

It is the goal of the pharmaceutical scientist to find a relationship between an in vitro characteristic of a dosage form and its in vivo performance. The earliest achievable in vitro characteristic thought to portend an acceptable in vivo performance was tablet and capsule disintegration. A test for disintegration was adopted in USP XIV (1950). At that time, no quantitative work was done in attempting to demonstrate such a relationship, especially in regard to in vivo product performance. However, advances in instrumental methods of analysis ultimately opened up prospects for this work. The disintegration test was recognized as being insufficiently sensitive by the USP-NF Joint Panel on Physiologic Availability, and in 1968 the Panel directed the identification of candidate articles for the first twelve official dissolution tests that used Apparatus 1.

The state of science is such that conduct of in vivo testing is necessary in the development and evaluation of dosage forms. Also, no product, including suspensions and chewable tablets, should be developed without dissolution or drug release characterization where a solid phase exists. This chapter sets forth, for products intended for human use, guidelines for characterizing a drug that include: (1) developing in vitro test methods for immediate-release and modified-release dosage forms, (2) designing in vivo protocols, and (3) demonstrating and assessing in vitro-in vivo correlations for modified-release dosage forms.

#### IN VITRO EVALUATION

##### Dissolution and Drug Release Testing—Method Development for Immediate-Release Dosage Forms

Dissolution testing is required for all solid oral Pharmacopeial dosage forms in which absorption of the drug is necessary for the product to exert the desired therapeutic effect. Exceptions are for tablets meeting a requirement for completeness of solution or for rapid (10 to 15 minutes) disintegration for soluble or radiolabeled drugs. The apparatus and procedure conform to the requirements and specifications given in the general chapter [Dissolution](#) (711). Generally, experiments are conducted at 37°.

The dissolution medium preferably is deaerated water or, if substantiated by the solubility characteristics of the drug or the formulation, a buffered aqueous solution (typically pH 4 to 8) or a dilute acid (0.001 N to 0.1 N hydrochloric acid) may be used. The usual volume of the medium is 500 to 1000 mL, with the use of greater volumes (up to 2000 mL) allowed for drugs having limited solubility. The quantity of medium used should be not less than 3 times that required to form a saturated solution of the drug substance. The significance of deaeration of the medium should be determined. Addition of solutes (i.e., surfactants) and electrolytes to aid in solubilization of the drug must be balanced against the loss of the discriminatory power of the test. The use of hydroalcoholic media is generally not favored. The use of such media should be supported by a documented in vitro-in vivo correlation. Conversely, it should be recognized that this discriminatory power could in some circumstances be excessive in that it may result in detection of differences in dissolution that are not clinically significant.

The choice of apparatus should be based on knowledge of the formulation design and actual dosage form performance in the in vitro test system. Since dissolution apparatuses tend to become less discriminating when operated at faster speeds, lower stirring speeds should be evaluated and an appropriate speed chosen in accordance with the test data. The most common operating speeds are 100 rpm for Apparatus 1 (basket) and 50 rpm for Apparatus 2 (paddle) for solid-oral dosage forms and 25 rpm for suspensions. A 40-mesh screen is used in almost all baskets, but other mesh sizes may be used when the need is documented by supporting data.

Apparatus 2 is generally preferred for tablets. Apparatus 1 is generally preferred for capsules and for dosage forms that tend to float or that disintegrate slowly. A sinker, such as a few turns of platinum wire, may be used to prevent a capsule from floating. Other types of sinker devices that achieve minimal coverage of dosage form surface are commercially available.

Where the use of a sinker device is employed, it is incumbent on the analyst to assure that the device used does not alter the dissolution characteristics of the dosage form.

Dissolution testing should be conducted on equipment that conforms to the requirements in the chapter [Dissolution](#) (711) and that has been calibrated with both the USP Salicylic Acid and Prednisone Calibrator Tablets. The method of analysis should be validated in accordance with the procedures given in the chapter [Validation of Compendial Procedures](#) (1225).

The test time is generally 30 to 60 minutes, with a single time point specification for pharmacopeial purposes. To allow for typical disintegration times, test times of less than 30 minutes should be based on demonstrated need. Industrial and regulatory concepts of product comparability and performance may require additional time points, and this may also be a feature required for product registration or approval. For registration purposes, a plot of percentage of drug dissolved versus time should be determined. Enough time points should be selected to characterize adequately the ascending and plateau phases of the dissolution curve.

Dissolution test times and specifications usually are established on the basis of an evaluation of dissolution profile data. Typical specifications for the amount of active ingredient dissolved, expressed as a percentage of the labeled content (Q), are in the range of 70% to 80% Q dissolved. A Q value in excess of 80% is not generally used, as allowance needs to be made for assay and content uniformity ranges.

For products containing more than a single active ingredient, dissolution normally should be determined for each active ingredient. Where a dissolution test is added to an existing monograph, the disintegration test is deleted. However, in the case of sublingual preparations, a short disintegration time may be retained as a monograph specification in addition to a dissolution requirement.

##### Dissolution and Drug Release Testing—Method Development for Modified-Release Dosage Forms

Drug release testing is required for all modified-release dosage forms in which absorption of the drug is necessary for the product to exert the desired therapeutic effect. The apparatus and procedure conform to the requirements and specifications given in the general chapter [Drug Release](#) (724).

The dissolution medium preferably is deaerated water or, if substantiated by the solubility characteristics of the drug or the formulation, buffered aqueous solutions (typically pH 4 to 8) or dilute acid (0.001 N to 0.1 N hydrochloric acid) may be used. (See above under Dissolution and Drug Release Testing—Method Development for Immediate-release Dosage Forms.) For modified-release dosage forms, the pH- and surfactant-dependence of the dosage form should be evaluated by in vitro testing in media of various compositions. The volume of medium will vary depending on the apparatus used and the formulation under test.

The choice of apparatus should be based on knowledge of the formulation design and actual dosage form performance in the in vitro test system. Apparatus 1 (basket) or Apparatus 2 (paddle) may be more useful at higher rotation frequencies (e.g., the paddle at 100 rpm). Apparatus 3 (reciprocating cylinder) has been found to be especially useful for bead-type modified-release dosage forms. Apparatus 4 (flow cell) may offer advantages for modified-release dosage forms that contain active ingredients having very limited solubility. Apparatus

(reciprocating disk) has been shown to have application to nondisintegrating oral modified-release dosage forms, as well as to transdermal dosage forms. Apparatus 5 (paddle over disk) and Apparatus 6 (cylinder) have been shown to be useful for evaluating and testing transdermal dosage forms.

At least three test times are chosen to characterize the in vitro drug release profile for Pharmacopeial purposes. Additional sampling times may be required for drug approval purposes. An early time point, usually 1 to 2 hours, is chosen to show that potential dose dumping is not probable. An intermediate time point is chosen to define the in vitro release profile of the dosage form, and a final time point is chosen to show essentially complete release of the drug. Test times and specifications are usually established on the basis of an evaluation of drug release profile data. For products containing more than a single active ingredient, drug release should be determined for each active ingredient.

Where a single set of specifications cannot be established to cover multisource monograph articles, application of a Case Three standard is appropriate. In Case Three, multiple drug release tests are included under the same monograph heading, and labeling requirements are included to indicate with which drug release test a specific product complies and, in some cases, the biological performance to be expected.

Drug release testing should be conducted on equipment that conforms to the requirements in the chapter [Drug Release](#) (724) and that has been calibrated with the appropriate USP calibrators. The method of analysis should be validated in accordance with the procedures given in the chapter [Validation of Compendial Procedures](#) (1225).

#### IN VIVO EVALUATION OF MODIFIED-RELEASE DOSAGE FORMS

In evaluating a modified-release product, a fundamental issue is the types of studies that should be performed to give reasonable assurance of safety and efficacy. While providing important information concerning the release characteristics of the drug from the dosage form, at present in vitro studies are most useful for such purposes as monitoring drug product stability and manufacturing process control. The assessment of safety and efficacy of a modified-release dosage form is best achieved through observing in vivo pharmacodynamics or pharmacokinetics. Moreover, where there is a well-defined, predictive relationship between the plasma concentrations of the drug or active metabolites and the clinical response (therapeutic and adverse), it may be possible to use plasma drug concentration data alone as a basis for the approval of a modified-release preparation that is designed to replace an immediate-release preparation.

The following guidelines are intended to provide guidance in drug substance evaluation and the design, conduct, and evaluation of studies involving modified-release dosage forms. While these guidelines will focus on oral drug delivery systems, the principles may be applicable to other routes of drug administration (e.g., transdermal, subcutaneous, intramuscular, etc.).

##### Characterization of Drug Substance

###### physicochemical properties

Physicochemical information necessary to characterize the drug substance in a modified-release dosage form should generally be no less than for the drug substance in an immediate-release dosage form. Additional physicochemical information may be needed on polymorphism, particle size distribution, solubility, dissolution rate, stability, and other release-controlling variables of the active drug entity under conditions that may react to the extremes of the physiologic environment experienced by the dosage form. For purposes of this chapter, active drug entity is taken to be the official drug substance.

###### pharmacokinetic properties

It is recommended to characterize thoroughly the input absorption profile of the active drug entity from a rapidly available preparation (an intravenous solution or oral solution or a well-characterized FDA-approved immediate-release drug product), which serves in turn as a reference to evaluate the input profile of the modified-release dosage form. This information together with the biological disposition characteristics for the active drug entity can characterize and predict changes in the bioavailability of the drug when input is modified as in the case of the modified-release dosage form. For example, if the active drug entity exhibits saturable first-pass hepatic metabolism, a reduction in systemic availability could result after oral administration if the input rate is decreased.

In designing an oral modified-release dosage form, it may be useful to determine the absorption of the active drug entity in various segments of the gastrointestinal tract (particularly in the colon in the case of dosage forms that may release drug in this region). The effects of food also may be important, and should be investigated.

###### disposition properties

The information required to characterize the processes of disposition of the active drug entity from a modified-release dosage form should include those generally determined for the same drug in an immediate-release dosage form. This may include the following:

1. Disposition parameters—clearance, volume of distribution, half-life, mean residence time, or model-dependent or noncompartmental parameters.
2. Linearity or characterization of nonlinearity over the dose or concentration range which could possibly be encountered.
3. Accumulation.
4. Metabolic profile and excretory organ dependence, with special attention to the active metabolites and active enantiomers of racemic mixtures.
5. Enter hepatic circulation.
6. Protein binding parameters and dialyzability.
7. The effects of age, gender, race, and relevant disease states.
8. Plasma/blood ratios.
9. A narrow therapeutic index or a clinical response that varies significantly as a function of the time of day.

###### pharmacodynamic properties

Prior to developing a modified-release dosage form, information described below should be gathered.

Concentration-response relationships should be available over a dose range sufficiently wide to encompass important therapeutic and adverse responses. In addition, the equilibration time<sup>1</sup> characteristics between plasma concentration and effect should be evaluated. These concentration-response relationships should be sufficiently characterized so that a reasonable prediction of the safety margin can be made if dose-dumping from the modified-release dosage form should occur. If there is a well-defined relationship between the plasma concentration of the active drug entity or active metabolites and the clinical response (therapeutic and adverse), the clinical performance of a new modified-release dosage form could be characterized by plasma concentration-time data. If such data are not available, clinical trials of the modified-release dosage form should be carried out with concurrent pharmacokinetic-pharmacodynamic measurements.

##### Characterization of the Dosage Form

###### physicochemical properties

The variables employed to characterize the physicochemical properties of the active drug entity as it exists or is discernible in the dosage form should be the same as those employed to characterize the drug substance. Solubility and dissolution profiles over a relevant pH range, usually from pH 1 to pH 7.4, should be obtained, with particular attention given to the effect of the formulation (as compared to the active drug entity). Characterization of formulations that are insoluble in aqueous systems may require the addition of sodium lauryl sulfate or other surfactant.

###### pharmacokinetic properties

The types of pharmacokinetic studies that should be conducted are a function of how much is known about the active drug entity, its clinical pharmacokinetic and biopharmaceutic properties, and whether pharmacokinetic studies are intended to be the sole basis for product approval. As a minimum, (1) a single-dose crossover study for each strength of a modified-release dosage form and (2) a multiple-dose, steady-state study using the highest strength of a modified-release dosage form are required to characterize the product. Some appropriate single-dose crossover and multiple-dose steady-state studies are described below.

In some modified-release capsule dosage forms, the strengths differ from each other only in the amount of identical beaded material contained in each capsule. In this case, a single-dose and a multiple-dose steady-state study at the highest dosage strength are sufficient. Other strengths may be characterized on the basis of comparative in vitro dissolution data.

The following pharmacokinetic studies would be needed for most modified-release dosage forms. Such studies may, in this instance, constitute the basis for characterization of the dosage form. If approval is to be sought without conducting clinical trials, it is recommended that there be preconsultation with the regulatory authorities to ensure that an adequate database exists for such approval.

The types of studies generally conducted can be categorized as follows.

Case A—

Case A applies to the original modified-release oral dosage form of an active drug entity already marketed in immediate-release form and for which extensive pharmacodynamic/pharmacokinetic data exist.

Single-dose Crossover Study—

A single-dose crossover study should include the following treatments: the modified-release dosage form administered under fasting conditions; a dosage form that is rapidly available administered under fasting conditions; and the modified-release dosage form administered at the same time as a high-fat meal (or another type of meal that has potential for causing maximum perturbation).

The study of food effects should include provision for control of the fluid intake (e.g., 6 to 8 oz.) and temperature (e.g., ambient) at the time of drug administration. The dosage form should be administered within 5 minutes after completion of the meal.

If there are no significant differences in the rate or extent of bioavailability (AUC, Cmax, and Tmax) as a function of the meal, then additional food effect studies are not necessary.

If significant differences in bioavailability are found, it is necessary to define how food affects the modified-release dosage form, as well as how the food-drug effect relates to time.

The purpose of these studies is twofold: first, to determine whether there is a need for labeling instructions describing special conditions for administration with respect to meals and second, to provide information concerning the pattern of absorption of the modified-release dosage form compared to that of the immediate-release dosage form. The drug input function should be defined for modified-release dosage forms.<sup>2</sup> This will aid in the development of an appropriate in vitro dissolution test. For dosage forms that exhibit high variability, replicate studies are recommended.

Use the following guidelines in evaluating food effect.

1. If no well-controlled studies have previously defined the effects of a concurrent high-fat meal on an immediate-release dosage form, studies should be performed to determine whether a food effect is a result of problems with the dosage form, i.e., food-related changes in release, or food effects that are unrelated to the dosage form, such as changes in the drug's absorption from the gastrointestinal tract or changes in the drug's disposition (i.e., distribution or elimination) that are independent of absorption. The cause of the food effect should be determined by conducting a single-dose crossover study comparing the solution (or immediate-release dosage form) under fed and fasting conditions. If there is no effect of food, then one would conclude that there are problems with the dosage form. If there is an effect of food, then one would conclude that these are unrelated to the dosage form.
2. The effect of timing on the food-drug effect should be tested by performing a four-way crossover study with the modified-release dosage form administered under the following treatment conditions: fasting, taken with a high-fat meal, 1 hour before a high-fat meal, and 2 hours after a high-fat meal.
3. If the food effect on an immediate-release dosage form is determined to result from changes in the dissolved drug's absorption from the gastrointestinal tract or from changes in drug disposition, studies should be designed to define the appropriate relationship between drug dosing and meals.
4. Alternative appropriate studies could be conducted if the applicant were to label the drug for administration with a meal that is not fat-loaded. In this case, an alternative meal composition should be considered.
5. The entire single-dose, modified-release absorption profile should be monitored. Where appropriate (e.g., in a multiple-dose study) for specific drugs and drug delivery systems, blood samples should be taken following breakfast on the second day, before the second dose is administered. This sampling schedule is particularly important for once-a-day products.
6. For delayed-release (enteric-coated) dosage forms, bioavailability studies to characterize adequately the food effects and to support the dosing claims stated in the labeling should be performed.

Multiple-dose, Steady-state Studies—

STUDY I— When data demonstrating linear pharmacokinetics exist for an immediate-release dosage form, a steady-state study should be conducted with the modified-release dosage form at one dose rate (preferably at the high end of the usual dose-rate range) using an immediate-release dosage form as a control. At least three trough-plasma drug concentration (Cmin) determinations should be made to ascertain that steady-state conditions have been achieved. Plasma-drug concentration determinations, over at least one dosing interval of the modified-release dosage form, should be made in each phase of the crossover study. It may be preferable (as in the case of rhythmic variation in absorption or disposition of the drug) to measure concentrations over an entire day in each phase. The presence or absence of circadian variation should be verified. The modified-release dosage form should produce an AUC that is equivalent to the immediate-release dosage form. The degree of fluctuation for the modified-release product should be the same as, or less than, that for the immediate-release dosage form given by the approved regimen. Appropriate concentration measurements should include unchanged drug and major active metabolites. For racemic drug entities, consideration should be given to the measurement of the active enantiomers [enantiomer/diastereomer distinction].

STUDY II— Where comparisons of the pharmacokinetic properties of an immediate-release dosage form at different doses are not available, or where the data show nonlinearity, steady-state crossover studies comparing effects of the modified-release dosage form with those of the immediate-release dosage form should be conducted at two different dose rates: one at the low end of the recommended dosing range and the second at the high end of the dosing range. In each case, the modified-release dosage form must meet the criteria described in Study I with respect to AUC and fluctuations in plasma drug concentrations. If there are significant differences between the modified-release dosage form and the immediate-release dosage form at either the low or the high dosing rate, these data alone are not adequate to characterize the product.

Data can be misleading when obtained from subjects with atypical drug disposition or physiologic characteristics, relative to the target population. Therefore, subject selection should be randomized or from an appropriate target population. If the modified-release dosage form is for use in a specific subpopulation (e.g., for children), it should be tested in that population. Regardless of whether a drug exhibits linear or nonlinear pharmacokinetics, the basis for characterization is equivalence of AUC and of the relative degree of fluctuation of concentrations of the modified-release and immediate-release dosage forms.

Steady-state studies in selected patient population groups or drug interaction studies may also be necessary, depending upon the therapeutic use of the drug and the types of individuals for whom the modified-release dosage form will be recommended. For drugs having narrow therapeutic indices, it may be necessary to perform more extensive plasma concentration measurements to determine the potential for unusual drug-release patterns in certain subpopulations. In such studies, it is advisable to perform more than one AUC measurement per patient to assess variability with both the modified-release and the immediate-release dosage forms.

Case B—

Case B applies to a non-oral, modified-release dosage form of an already marketed active drug entity for which extensive pharmacodynamic/pharmacokinetic data exist.

Case A studies (omitting the food effect studies) would be appropriate for the evaluation of a modified-release dosage form designed for a non-oral route of administration if the pattern of biotransformation to active metabolites is identical for the two routes. If the biotransformation patterns are different, then clinical efficacy studies should be performed with the modified-release dosage form. In addition, special studies may be necessary to assess specific risk factors related to the dosage form (e.g., irritation and/or sensitization at the site of application).

Case C—

Case C applies to a generic equivalent of an approved modified-release dosage form.

A generic equivalent of an approved modified-release dosage form should be bioequivalent to the standard modified-release dosage form in its rate and extent of availability (i.e., AUC, Cmax, Cmin, and degree of fluctuation) in crossover single-dose and steady-state studies. For an oral modified-release dosage form, the food studies described under Case A should

also be performed.

#### Statistical Analysis

An appropriate statistical method should be selected. (See [In Vivo Bioequivalence Guidances \(1090\)](#)).

The currently accepted criteria in the United States for equivalence for most dosage forms require that the mean pharmacokinetic parameters of the test dosage form should be within 80% to 125% of the reference dosage form using the 90% confidence interval (or, equivalently, the two-sided test procedure,  $P = 0.05$ ), and the upper and lower bounds must be within the 90% confidence interval.

### IN VITRO-IN VIVO CORRELATIONS

The term in vitro-in vivo correlation first appeared in pharmaceutical literature as a result of the awareness of the concepts of bioavailability and of in vitro dissolution rate determinations. The term in vitro-in vivo correlation refers to the establishment of a rational relationship between a biological property, or a parameter derived from a biological property produced by a dosage form, and a physicochemical property or characteristic of the same dosage form. The biological properties most commonly used are one or more pharmacokinetic parameters, such as  $C_{max}$  or AUC, obtained following the administration of the dosage form. The physicochemical property most commonly used is a dosage form's in vitro dissolution behavior (e.g., percent of drug released under a given set of conditions). The relationship between the two properties, biological and physicochemical, is then expressed quantitatively.

With the proliferation of modified-release products, it becomes necessary to examine the concept of in vitro-in vivo correlation in greater depth. Unlike immediate-release dosage forms, modified-release products cannot be characterized using a single-time point dissolution test. Furthermore, with a modified-release product a patient is to experience a specific plasma level curve covering a finite time period, usually 12 to 24 hours. There must be some in vitro means of assuring that each batch of the same product will perform identically in vivo. An in vitro-in vivo correlation would satisfy this need. Initially it was thought that developing a meaningful correlation for immediate-release dosage forms would be an easier task than for modified-release products. However, because of the nature of the principles upon which each type is based, it is believed that an in vitro-in vivo correlation is more readily defined for modified-release dosage forms.

#### Modified-Release Dosage Forms general considerations

Initial attempts at developing in vitro-in vivo correlations of modified-release products utilized the same concepts as those employed with immediate-release dosage forms. Thus, numerous attempts have been made to correlate one or more pharmacokinetic parameters, determined from in vivo studies of a product, with the amount released in a given time in an in vitro dissolution test. These were essentially single-point correlations. Such relationships might indicate that increasing or decreasing the in vitro dissolution rate of the modified-release dosage form would result in a corresponding directional change in the product's performance. However, they revealed little about the overall plasma level curve, which is a major factor for drug performance in the patient.

The recognition and utilization of deconvolution techniques as well as statistical moment calculations represented a major advance over the single-point approach in that these two methodologies utilize all of the dissolution and plasma level data available to develop the correlations. Therefore, there are at least three correlation techniques (i.e., deconvolution, statistical moment, and single point), available to the pharmaceutical scientist. There are marked differences in the quality of the correlation obtained with each procedure. Thus, these methods have been categorized and are discussed in terms of the advantages of each along with the resulting potential utility as a predictive tool for the pharmaceutical scientist.

### CORRELATION LEVELS

Three correlation levels have been defined and categorized in descending order of usefulness. The concept of correlation level is based upon the ability of the correlation to reflect the entire plasma drug concentration-time curve that will result from administration of the given dosage form. It is the relationship of the entire in vitro dissolution curve to the entire plasma level curve that defines the correlation.

Level A— This level is the highest category of correlation. It represents a point-to-point relationship between in vitro dissolution and the in vivo input rate of the drug from the dosage form. This latter factor is sometimes referred to as in vivo dissolution. In such a correlation, the in vitro dissolution and in vivo input rate curves are either directly superimposable or may be made to be superimposable by the use of a constant offset value. The mathematical description for both curves is the same. Such a procedure is most applicable to modified-release systems that demonstrate an in vitro release rate that is essentially independent of the typical dissolution media usually employed in pharmaceuticals. However, this is not a requirement for a Level A correlation. With this correlative procedure, a product's in vitro dissolution curve is compared to its in vivo input curve (i.e., the curve produced by deconvolution of the plasma level data). This may be done by use of mass balance model-dependent techniques, such as the Wagner-Nelson procedure or the Loo-Riegelman method, or by model-independent, mathematical deconvolution.

The advantages of a Level A correlation are as follows:

- A point-to-point correlation is developed. This is not found with any other correlation level. It is developed using every plasma level and dissolution point that has been generated. Thus, it reflects the complete plasma level curve. As a result, in the case of a Level A correlation, an in vitro dissolution curve can serve as a surrogate for in vivo performance. Therefore, a change in manufacturing site, method of manufacture, raw material supplies, minor formulation modification, and even product strength using the same formulation can be justified without the need for additional human studies.
- A truly meaningful (in vivo indicating) quality control procedure, which is predictive of a dosage form's performance, is defined for the dosage form.
- The extremes of the in vitro quality control standards can be justified by a convolution or deconvolution procedure.

Level B— Utilizes the principles of statistical moment analysis. The mean in vitro dissolution time is compared to either the mean residence time or the mean in vivo dissolution time. Like correlation Level A, Level B utilizes all of the in vitro and in vivo data but is not considered to be a point-to-point correlation because it does not reflect the actual in vivo plasma level curve, since there are a number of different in vivo curves that will produce similar mean residence time values. For this reason, unlike the case of a Level A correlation, one cannot rely upon a Level B correlation alone to justify formulation modification, manufacturing site change, excipient source change, etc. In addition, in vitro data from such a correlation could not be used to justify the extremes of quality control standards.

Level C— This category relates one dissolution time point ( $t_{50\%}$ ,  $t_{90\%}$ , etc.) to one pharmacokinetic parameter such as AUC,  $C_{max}$ , or  $T_{max}$ . It represents a single point correlation. It does not reflect the complete shape of the plasma level, which is the critical factor that defines the performance of modified-release products. Since this type of correlation is not predictive of actual in vivo product performance, it is generally only useful as a guide in formulation development or as a production quality control procedure. Because of its obvious limitations, a Level C correlation has limited usefulness in predicting in vivo drug performance and is subject to the same caveats as a Level B correlation in its ability to support product and site changes as well as justification of quality control standard extremes.

developing a correlation

This chapter does not define the only procedures for developing an in vitro-in vivo correlation, as any well-designed and scientifically valid approach would be acceptable. To assist the pharmaceutical scientist, one possible procedure for developing a Level A correlation is described below.

- The plasma level or urinary excretion data obtained in the definitive bioavailability study of the modified-release dosage form are treated by a deconvolution procedure. The resulting data may represent the drug input rate of the dosage form. It is also considered to represent in vivo dissolution when the rate-controlling step of the dosage form is its dissolution rate (i.e., drug absorption, after it has dissolved, is considered to be instantaneous). Any deconvolution procedure (i.e., mass balance or mathematical deconvolution) will produce acceptable results.
- The biobatch<sup>3</sup> is subjected to in vitro dissolution evaluation, and the effect of varying the dissolution conditions investigated. Some of the variables that can be studied are the apparatus (it is preferable to use official apparatus), mixing intensity, and dissolution medium (pH, enzymes, surfactants, osmotic pressure, ionic strength, etc.). It is not always necessary to study the dosage form's dissolution behavior under all of the conditions indicated. The number of conditions investigated will depend largely on whether a correlation can be found with the in vitro results obtained under the more commonly investigated conditions such as apparatus, agitation intensity, or dissolution medium and

pH value. Each formulation and every drug represents an individual challenge. The in vitro evaluation of the dosage form should be performed regardless of the correlation level being developed.

- The in vitro dissolution curve is then compared to the drug input rate curve. This can be performed by various methods. Simply positioning one curve on the other can often indicate the existence of a correlation. This may then be quantified by defining the equation for each curve and comparing the corresponding constants. The simplest way to demonstrate a correlation is to plot the fraction absorbed in vivo versus the fraction released in vitro. With a Level A correlation, this relationship is often linear with a slope of 1. The intercept may or may not be 0 depending upon whether there is a lag time before the system begins to release drug in vivo, or the absorption rate is not instantaneous resulting in the presence of some finite quantity of dissolved but unabsorbed drug. In either case, it is a point-to-point or a Level A correlation when the relationship is linear with a slope of 1. This indicates that the curves are essentially superimposable.
- If from the studies indicated in the in vitro dissolution evaluation above, the modified-release dosage form exhibits dissolution behavior that is independent of the variables studied, and a Level A correlation is demonstrated when the in vitro dissolution curve is compared to the drug input rate curve, it is likely that the correlation is general and can be extrapolated within a reasonable range for that formulation of the active drug entity. If, however, the dosage form exhibits dissolution behavior that varies with the in vitro conditions, it must be determined which set of dissolution conditions best correlates with in vivo performance. One can then establish whether the correlation is real or an artifact. This is achieved by preparing at least two formulations having significantly different in vitro behavior. One should demonstrate a more rapid release and the other a slower release than the biobatch. A pilot BA-BE study should be performed with these formulations, and the previously established correlation demonstrated for both. The formulation modifications of these batches should be based upon formulation factors that would be expected to influence the product's modified-release mechanism, and modification of these formulation factors are expected to influence the dosage form's release rate.
- Once a Level A correlation is established, it is possible that in vitro testing may be utilized for establishing the effects of manufacturing modifications such as minor formulation changes, manufacturing site and equipment change, alternative excipient suppliers, and a change in dosage form strength in the same formulation. It is questionable whether such an extrapolation with Level B and C correlations is possible.

#### Establishment of Dissolution Specification Ranges

It is relatively easy to establish a multipoint dissolution specification for a modified-release dosage form. The dissolution behavior of the biobatch may be used to define the amount to be released at each time point. The difficulty arises in the variation to be allowed around each time point. In the case of a Level A correlation, this may be done in two ways, both of which utilize the in vitro-in vivo correlation: convolution and deconvolution.

##### convolution

Reasonable upper and lower dissolution values are selected for each time point established from the biobatch. Historically, dissolution specifications have been selected by using the average dissolution of the development batches, with a range of  $\pm 2.5$  to 3 standard deviations. It is now expected that the average dissolution values are approximately the same as those of the biobatch. The dissolution curves defined by the upper and lower extremes are convoluted to project the anticipated plasma level curves that would result from administration of these formulations to the same panel to which the biobatch was administered. If the resulting plasma level data fall within the 95% confidence intervals obtained in the definitive BA-BE study, these ranges can be considered to be acceptable. An alternative acceptance approach that has been suggested is that when the therapeutic window for a drug has been defined, one may establish an upper and lower limit if the convolution results fall within the therapeutic window, even if they fall outside the confidence interval. If they fall outside the intervals, a more limited range must be established. This should be continued until the predicted values meet the desired ranges.

##### deconvolution

An acceptable set of plasma-level data is established both for a batch of material demonstrating a more rapid release and for one demonstrating a slower release than that of the biobatch. These may be selected by using the extremes of the 95% confidence intervals or  $\pm 1$  standard deviation of the mean plasma level. These curves are then deconvoluted, and the resulting input rate curve is used to establish the upper and lower dissolution specifications at each time point.

In the case of Level B and C correlations, batches of product must be made at the proposed upper and lower limits of the dissolution range, and it must be demonstrated that these batches are acceptable by performing a BA-BE study.

#### Immediate-Release Dosage Forms

##### general considerations

Since the mechanisms for release of drug from modified-release dosage forms are more complex and variable than those associated with immediate-release dosage forms, it would be anticipated that an in vitro-in vivo correlation would be easier to develop with the later formulations. Unfortunately, most of the correlation efforts to date with immediate-release dosage forms have been based on the correlation Level C approach, although there also have been efforts employing statistical moment theory (Level B). Although it is conceivable that the same Level A correlation approach may be utilized with immediate-release dosage forms, until data have been gathered to support this concept, Level B and Level C are the best approaches that can be recommended with these dosage forms.

1 Equilibration time is a measure of the time-dependent discontinuity between measured plasma concentrations and measured effects. The discontinuity is more often characterized by the degree of hysteresis observed when the effect-concentration plot for increasing concentrations is compared with that for decreasing concentrations. Where the equilibration time is very short (i.e., rapid equilibration with no active metabolites generated), there will be little or no hysteresis. That is, the same effect will be observed for a given concentration independent of the interval between the time of dosing and the time that measurements are made.

2 Wagner-Nelson, Loo-Riegelman, and other deconvolution methods are found in textbooks on biopharmaceutics.

3 The batch that was used in the pivotal bioavailability study.

#### 1090 IN VIVO BIOEQUIVALENCE GUIDANCES<sup>1</sup>

This chapter is divided into two sections that provide guidances related to the general conduct of bioequivalence tests and to bioavailability protocols for specific drugs. These statements were prepared by the Food and Drug Administration, Office of Generic Drugs (FDA, OGD), Division of Bioequivalence, and presented herein. For general background information on related issues, refer to [In Vitro and In Vivo Evaluation of Dosage Forms](#) 1088.

#### DRUG PROTOCOLS

##### Alprazolam Tablets—In Vivo Bioequivalence and In Vitro Dissolution Testing<sup>4</sup>

Clinical Usage/Pharmacology—Alprazolam is widely used in the management of anxiety disorders, panic disorder, social phobia, and depression. It is a triazolo analog of the 1,4-benzodiazepine class of compounds acting on the central nervous system (CNS). The exact mechanism of action of alprazolam is unknown; however, published literature indicates that this class of drugs exerts effects by binding to stereospecific receptors at several sites within the central nervous system. The drug effect is dose-related. The daily dose of alprazolam depends on the individual patient, and averages 1.5 to 4 mg. Although a major metabolite,  $\alpha$ -hydroxyalprazolam, shows some pharmacological activity, no alprazolam metabolites possess any clinically important role, and they do not accumulate to any significant degree.

Pharmacokinetics— Alprazolam is readily absorbed (more than 90%) after oral administration and is distributed widely with a volume of distribution of approximately 1 L per kg in healthy men and women. Peak concentrations in the plasma occur 1 to 2 hours after administration. With doses ranging from 0.5 to 3.0 mg given on an empty stomach, plasma peak levels of 8.0 to 37 ng per mL were observed. The mean plasma elimination half-life of alprazolam has been reported to be about 11.2 hours (range: 6.3 to 26.9 hours) in healthy adults.

The drug absorption is slower when alprazolam is taken after a meal than on an empty stomach, but total absorption is unchanged.

in vivo bioequivalence studies<sup>5</sup>

Product Information—

FDA Designated Reference Product: Xanax® (Upjohn) 1-mg tablets.

Batch Size— The test batch or lot must be manufactured under production conditions and must be of a size that is at least 10% of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.

Potency— The assayed potency of the reference product should not differ from that of the test product by more than 5%.

Type of Study Required— A single-dose, randomized, fasting, two-period, two-treatment, two-sequence crossover study comparing equal doses of the test and reference products.

Recommended Protocol for Conducting a Single-Dose, Fasted Bioequivalence Study—

Objective— The objective is to compare the rate and extent of absorption of a generic formulation with that of a reference formulation when given as equal labeled doses.

Design— The study design is a single-dose, two-treatment, two-period, two-sequence crossover with a 1-week washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

Facilities— The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

Selection of Subjects— The sponsors should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 24 subjects be used in this study. Subjects should be healthy, preferably nonsmoking, volunteers aged 18 to 50 years and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of acceptable medical history, physical examination, and clinical laboratory test results. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. If smokers are included, they should be identified as such. Written, informed consent must be obtained from all study participants before they are accepted into the study.

Procedure— Following an overnight fast of at least 10 hours, subjects should be administered a single dose of the test or reference product with 240 mL of water.

Restrictions— Study volunteers should observe the following restrictions:

- a. Water may be taken except for 1 hour before and after drug administration, when no liquid is allowed other than that needed for drug dosing.
- b. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- c. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- d. Subjects should take no Rx medications, including oral contraceptives, or OTC medications beginning 2 weeks before drug administration and until after the study is completed.

Blood Sampling— Venous blood samples should be collected pre-dose (0 hours) and at 0.25, 0.50, 0.75, 1.0, 1.50, 2.0, 2.50, 3.0, 4.0, 6.0, 8.0, 12, 24, 36, 48, and 72 hours post-dose. Plasma should be separated promptly and immediately frozen until assayed. Following at least a minimum 1-week washout period, subjects should begin the second phase of the study.

Analytical Methods— Alprazolam should be assayed using a suitable method fully validated with respect to adequate sensitivity, specificity, linearity, recovery, and accuracy and precision (both within and between days). Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined. Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

Statistical Analysis of Pharmacokinetic Data (Plasma)— See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances.

Clinical Report, Side Effects, and Adverse Reactions— Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions to the study formulations should be reported.

Retention of Samples— The laboratory conducting the bioequivalence testing should retain an appropriately identified reserve sample of both the test and reference products used to perform the in vivo bioequivalence study for approval of the application. Each reserve sample should consist of at least 200 dosage units and should be retained for a period of not less than 5 years following approval of the application. For more information on retention of bioequivalence samples, refer to 21 CFR 320.63.

in vitro testing requirements

Dissolution Testing— Conduct dissolution testing on 12 dosage units of the test product and the reference product, employing the biostudy lots. The current official USP dissolution method (see [Dissolution](#) (711)) should be followed and should be referenced by the sponsor. The following method and tolerances are currently recommended for this product:

Medium: phosphate buffer solution (pH 6.0); 500 mL.

Apparatus 1: 100 rpm.

Times: 10, 20, 30, and 45 minutes.

Procedure— Use USP if available, or other validated method (see [Validation of Compendial Procedures](#) (1225)).

Tolerances (Q): not less than 80% in 30 minutes.

The percentage of label claim dissolved at each specified testing interval should be reported for each individual dosage unit. The mean percentage dissolved, the range (highest, lowest) of dissolution, and the coefficient of variation (relative standard deviation) should be reported.

Content Uniformity Test— Content uniformity testing on the test product lots should be performed as described in USP.

waiver requirements

Waiver of in vivo bioequivalence study requirements for the 0.25-, 0.5-, and 2-mg strengths of the generic product may be granted pursuant to 21 CFR 320.22(d)(2), provided the following conditions are met:

1. The 0.25-, 0.5-, and 2-mg strengths are proportionally similar in both active and inactive ingredients to another strength (1 mg), which has been demonstrated to be bioequivalent to a reference (1 mg) product in vivo.
2. The 0.25-, 0.5-, and 2-mg strengths of the generic product meet dissolution requirements.
3. The drug product follows linear kinetics over its range of available strengths.

Bumetanide Tablets—In Vivo Bioequivalence and In Vitro Dissolution Testing<sup>4</sup>

Clinical Usage/Pharmacology— Bumetanide is a potent diuretic indicated for the treatment of edema associated with congestive heart failure and hepatic and renal disease, including the nephrotic syndrome. Bumetanide is contraindicated in anuria, hepatic coma, states of severe electrolyte depletion, and in patients hypersensitive to the drug.

The major site of action of bumetanide is the ascending limb of the loop of Henle, where it inhibits the sodium-potassium-2 chloride absorptive pump. The usual daily dosing range for bumetanide is 0.5 to 2.0 mg.

**Pharmacokinetics**— Bumetanide is reported to be readily absorbed from the gastrointestinal (GI) tract with a  $T_{max}$  of 0.5 to 2 hours, and a bioavailability of about 80% to 90%. Several pharmacokinetic studies have shown that bumetanide, administered orally, is eliminated rapidly in humans, with a half-life of between 1 and 2 hours. Plasma protein-binding is approximately 95%. Oral administration of bumetanide resulted in 36% to 60% recovery of the unchanged drug from urine. The volume of distribution ( $V_d$ ) is approximately 0.2 L per kg. Following oral administration of bumetanide, the onset of diuresis occurs in 30 to 60 minutes. Peak activity is reached between 0.5 and 3 hours.

#### in vivo bioequivalence studies<sup>5</sup>

##### Product Information—

FDA Designated Reference Product: Bumex® (Roche Laboratories) 2.0-mg tablets.

**Batch Size**— The test batch or lot must be manufactured under production conditions and must be of a size that is at least 10% of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.

**Potency**— The assayed potency of the reference product should not differ from that of the test product by more than 5%.

**Type of Study Required**— A single-dose, randomized, two-period, two-treatment, two-sequence crossover study under fasting conditions comparing equal doses of the test and reference products.

##### Recommended Protocol for Conducting a Single-Dose, Fasted Bioequivalence Study—

**Objective**— The objective is to compare the rate and extent of absorption of a generic formulation with that of a reference formulation when given as equal labeled doses.

**Design**— The study design is a single-dose, two-treatment, two-period, two-sequence crossover with at least a three-day washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

**Facilities**— The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

**Selection of Subjects**— The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 24 subjects be used in this study. Subjects should be healthy, preferably nonsmoking, volunteers aged 18 to 50 years and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of acceptable medical history, physical examination, and clinical laboratory test results. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. If smokers are included, they should be identified as such. Written, informed consent must be obtained from all study participants before they are accepted into the studies.

**Procedure**— Following an overnight fast of at least 10 hours, subjects should be administered a single dose (2.0 mg) of the test or reference product with 240 mL of water. The subjects should drink 240 mL of water at the following times: -2, -1, 0, 1, 2, 4, 6, 8, and 10 hours relative to dosing.

##### Restrictions— Study volunteers should observe the following restrictions:

- a. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- b. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- c. Subjects should take no Rx medications, including oral contraceptives, beginning 2 weeks and no OTC medications beginning 1 week before drug administration and until after the study is completed.

**Blood Sampling**— Venous blood samples in a volume sufficient for sample analysis and anticoagulated as appropriate should be collected pre-dose (0 hours) and at 0.25, 0.50, 0.75, 1.0, 1.25, 1.50, 1.75, 2.0, 2.50, 3, 4, 5, 6, 8, and 12 hours post-dose. Plasma should be separated promptly, immediately frozen, and stored at  $-20^{\circ}\text{C}$  until assayed. Following a minimum 1-week washout period, subjects should begin the second phase of the study.

**Urine Sampling**— Urine may be collected over the following time intervals: -2 to 0, 0 to 1, 1 to 2, 2 to 4, 4 to 6, 6 to 8, 8 to 10, and 10 to 12 hours post-dosing. The urine volume and pH should be noted. One 50-mL aliquot should be stored refrigerated for possible analysis of sodium and potassium. A 15-mL sample should be stored frozen at  $-20^{\circ}\text{C}$  for possible bumetanide assay.

**Analytical Methods**— High-performance liquid chromatographic methods have been reported for assaying bumetanide in human plasma and urine.

Bumetanide should be assayed using a suitable method fully validated with respect to stability, sensitivity, specificity, linearity, recovery, and accuracy and precision (both within and between days). Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined. Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

**Statistical Analysis of Pharmacokinetic Data (Plasma)**— See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances.

**Diuretic Effects and Bumetanide Urinary Excretion Data**— Urine samples may be analyzed to determine the following parameters:

- a. The mean rate of excretion of sodium, potassium, water, and bumetanide for each collection period.
- b. The maximum excretion rate (excretion rate calculated for that time interval during which the rate is highest) for sodium, potassium, water, and bumetanide.
- c. Time to maximum excretion rate for sodium, potassium, water, and bumetanide.
- d. Cumulative excretion of sodium, potassium, water, and bumetanide over all sampling time intervals.

**Clinical Report, Side Effects, and Adverse Reactions**— Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions to the study formulations should be reported.

**Retention of Samples**— The laboratory conducting the bioequivalence testing should retain an appropriately identified reserve sample of both the test product and the reference standard used to perform the in vivo bioequivalence studies for approval of the application. Each reserve sample should consist of at least 200 dosage units and should be retained for a period of not less than 5 years following approval of the application. For more information on retention of bioequivalence samples, refer to 21 CFR 320.63.

#### in vitro testing requirements

**Dissolution Testing**— Conduct dissolution testing on 12 dosage units of the test product and the reference product, employing the biostudy lots. The current official USP dissolution method (see [Dissolution](#) (711)) should be followed and should be referenced by the sponsor. The following method and tolerances are currently recommended for this product: Medium: water; 900 mL.

Apparatus 2: 50 rpm.

Times: 10, 20, 30, and 45 minutes.

**Procedure**— Use USP if available, or other validated method (see [Validation of Compendial Procedures](#) (1225)).

Tolerances (Q): not less than 85% in 30 minutes.

The percentage of label claim dissolved at each specified testing interval should be reported for each individual dosage unit. The mean percentage dissolved, the range (highest, lowest) of dissolution, and the coefficient of variation (relative standard deviation) should be reported.

Content Uniformity Test—Content uniformity testing on the test product lots should be performed as described in USP.

waiver requirements

Waiver of in vivo bioequivalence study requirements for the 0.5- and 1.0-mg strengths of the generic product may be granted pursuant to 21 CFR 320.22(d)(2), provided the following conditions are met:

1. The 0.5- and 1-mg tablets are proportionally similar in both active and inactive ingredients to the 2-mg tablet, which has been demonstrated to be bioequivalent to the reference 2-mg product in vivo.
2. The 0.5- and 1-mg tablets of the generic product meet dissolution test requirements.

#### Buspirone Hydrochloride Tablets—In Vivo Bioequivalence and In Vitro Dissolution Testing<sup>4</sup>

**Clinical Pharmacology/Usage**— Buspirone hydrochloride is an anti-anxiety agent. Clinically it is effective in the management of anxiety disorders or short-term relief of symptoms of anxiety. Buspirone has no anticonvulsant or muscle relaxant activity and has little sedative effect. It does not substantially affect psychomotor function. There is no evidence that the drug causes either physical or psychological dependence. The mechanism of action of buspirone is not known. Some in vitro preclinical studies indicate that buspirone has a high affinity for serotonin (5-HT1A) receptors and a moderate affinity for brain D2 receptors.

For the management of anxiety disorders, the usual initial adult dosage of buspirone is 10 to 15 mg daily, usually in 2 or 3 divided doses. Dosage is increased, as necessary, in increments of 5 mg daily to achieve an optimal therapeutic response. The maximum daily dose should not exceed 60 mg per day.

**Pharmacokinetics**— Buspirone is rapidly and almost completely absorbed from the GI tract. The drug undergoes extensive first-pass metabolism, with about 4% of a dose reaching the systemic circulation unchanged following oral administration. Following oral administration of a single dose of 20 mg in healthy volunteers, peak plasma buspirone concentrations of 1 to 6 ng per mL have been observed to occur within 40 to 90 minutes. Plasma concentrations of unchanged buspirone are low and exhibit substantial interindividual variation with oral administration of the drug. Approximately 95% of buspirone is bound to plasma proteins.

Buspirone is rapidly metabolized by oxidation to produce several hydroxylated derivatives and a pharmacologically active metabolite, 1-pyrimidinylpiperazine (1-PP). Because of rapid metabolism, less than 1% of the parent drug is excreted unchanged in the urine. The pharmacologically active metabolite has about 20% to 25% of the anxiolytic activity of buspirone. In humans, blood concentrations of 1-PP remain low even after chronic administration of buspirone. The contribution of 1-PP to the pharmacologic and toxic effect thus remains to be elucidated fully.

The average elimination half-life of unchanged buspirone after single doses of 10 to 40 mg is reported to be 2 to 3 hours. Buspirone exhibits linear kinetics following administration of doses (10 to 40 mg) in the therapeutic range. Although food increases the bioavailability of buspirone by decreasing first-pass metabolism, the total amount of drug (changed and unchanged) in plasma is not affected.

#### in vivo bioequivalence studies<sup>5</sup>

Product Information—

FDA Designated Reference Product: Buspar® (Bristol-Meyers Squibb) 10-mg tablet.

**Batch Size**— The test batch or lot must be manufactured under production conditions and must be of a size at least 10% that of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.

**Potency**— The assayed potency of the reference product should not differ from that of the test product by more than 5%.

#### Types of Studies Required—

1. A single-dose, randomized, two-period, two-treatment, two-sequence crossover study under fasting conditions comparing equal doses of the test and reference products.
2. A single-dose, randomized, three-treatment, three-period, six-sequence crossover, limited food effects study comparing equal doses of the test and reference products when administered immediately following a standard high-fat breakfast.

#### Recommended Protocol for Conducting a Single-Dose, Fasted Bioequivalence Study—

**Objective**— The objective is to compare the rate and extent of absorption of buspirone and 1-PP from a generic formulation with that from a reference formulation when given as equal labeled doses.

**Design**— The study design is a single-dose, two-treatment, two-period, two-sequence crossover with a 1-week washout period between Phase I and Phase II dosing or a single-dose, two-treatment, four-period, four-sequence replicate design study with a 1-week washout period between each phase of dosing. An equal number of subjects should be randomly assigned to each of the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

**Facilities**— The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

**Selection of Subjects**— The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. Subjects should be healthy, preferably nonsmoking, volunteers aged 18 to 55 and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of acceptable medical history, physical examination, and clinical laboratory test results. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. If smokers are included, they should be identified as such. Written, informed consent must be obtained from all study participants before they are accepted into the study.

**Procedure**— Following an overnight fast of at least 10 hours, subjects should be administered four 10-mg tablets of the test or reference product with 240 mL of water.

**Restrictions**— Study volunteers should observe the following restrictions:

- a. Water may be taken, except for 1 hour before and after drug administration, when no liquid is allowed other than that needed for drug dosing.
- b. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- c. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- d. Subjects should take no Rx medications, including oral contraceptives, beginning 2 weeks and no OTC medications beginning 1 week before drug administration and until after the study is completed.

**Blood Sampling**— Venous blood samples should be collected pre-dose (0 hours) and at 0.25, 0.50, 0.75, 1, 1.5, 2, 2.5, 3, 4, 6, 7, 8, 12, and 24 hours post-dose. Plasma should be separated promptly and immediately frozen until assayed. Following a minimum 1-week washout period, subjects should begin the second phase of the study.

**Subject Monitoring**— Blood pressure and pulse rate should be monitored hourly during the first 4 hours of the study. Subjects with a heart rate less than 45 bpm or greater than 110 bpm should have an electrocardiogram (lead II) performed and have their pulse monitored hourly. Subjects should report any unusual symptoms observed during the study. Subjects should be periodically questioned during each phase of the study for any unusual symptoms experienced after drug administration.

**Analytical Methods**— Buspirone and 1-PP should be assayed using a suitable method fully validated with respect to adequate sensitivity, specificity, linearity, recovery, accuracy, and precision (both within and between days). Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined.

...chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

Statistical Analysis of Pharmacokinetic Data— See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances.

**Limited Food Effects Study—**

**Objective**— The objective is to compare the rate and extent of absorption of buspirone and 1-PP from a generic formulation with that from a reference formulation under nonfasting conditions and to compare the rate and extent of absorption of the drug from a generic formulation under fasting and nonfasting conditions when given as equal labeled doses.

**Design**— The study design is a single-dose, three-treatment, three-period, six-sequence crossover with a 1-week washout period between Phase I and Phase II, and Phase II and Phase III.

The limited food effects study (with a minimum of 12 subjects) should be performed in the same manner as the single-dose study under fasting conditions, with the following exceptions:

**Procedure**— An equal number of subjects should be assigned to each of the 6 dosing sequences possible in a three-treatment, three-period study design. Each subject will receive the following treatments:

TREATMENT 1: Generic product, four 10-mg tablets administered after a standard high-fat breakfast.

TREATMENT 2: Reference product, four 10-mg Buspar® tablets administered after a standard high-fat breakfast.

TREATMENT 3: Generic product, four 10-mg tablets administered under fasting conditions.

Following a 10-hour fast, the subjects receiving treatments under fed conditions should be served a standard high-fat breakfast. The subjects should have 30 minutes to finish the entire breakfast and then should immediately receive Treatment 1 or Treatment 2, taken with 240 mL of water. Subjects receiving the treatment under fasting conditions should receive Treatment 3, taken with 240 mL of water only. The same lots of the test and reference products should be used in the fasted and fed studies. No food should be allowed for at least 4 hours post-dose, with water allowed after the first hour. Subjects should be served scheduled standardized meals throughout the study, and the same meals should be served during all phases of the study.

**Statistical Analysis**— In general, a comparable food effect will be assumed if the AUC0-T, AUC0-, and Cmax mean values for the test product administered under fed conditions are within 20% of the respective mean values obtained for the reference product administered under fed conditions.

**Clinical Report, Side Effects, and Adverse Reactions**— Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions and side effects to the study formulations should be reported.

**Retention of Samples**— The laboratory conducting the bioequivalence testing should retain appropriately identified reserve samples of both the test and reference products used to perform the in vivo bioequivalence studies for approval of the application. Each reserve sample should consist of at least 200 dosage units or 5 times the amount needed for complete release testing, whichever is greater, and should be retained for a minimum of 5 years following approval of the application. For more information on retention of bioequivalence samples, refer to 21 CFR 320.63.

**in vitro testing requirements**

**Dissolution Testing**— Conduct dissolution testing on 12 dosage units of the test and reference products, employing the biostudy lots. The current official USP dissolution method (see [Dissolution \(711\)](#)) should be followed and should be referenced by the sponsor. The following times should be used to determine the dissolution profile. Times: 10, 20, 30, and 45 minutes.

The percentage of label claim dissolved at each specified testing interval should be reported for each individual dosage unit. The mean percentage dissolved, the range of dissolution (highest, lowest), and the coefficient of variation (relative standard deviation) should be reported.

**Content Uniformity Test**— Content uniformity testing on the test and reference product lots should be performed as described in USP.

**waiver requirements**

Waiver of in vivo bioequivalence study requirements for the 5-mg strength of the generic product may be granted pursuant to 21 CFR 320.22(d)(2) provided the following conditions are met:

1. The 5-mg tablet is proportionally similar in both active and inactive ingredients to the firm's 10-mg tablet, which has been demonstrated to be bioequivalent to the reference product in vivo.
2. The 5-mg tablet of the generic product meets dissolution test requirements.

**Captopril Tablets—In Vivo Bioequivalence and In Vitro Dissolution Testing<sup>4</sup>**

**Clinical Usage/Pharmacology**— Captopril, an antihypertensive, inhibits the enzyme that converts angiotensin I, a relatively inactive decapeptide, to angiotensin II, a potent endogenous vasoconstrictor substance. This enzyme, angiotensin converting enzyme, or ACE, is a peptidyldipeptide carboxy hydrolase.

The recommended initial dosage for treatment of hypertension is 25 mg twice a day (b.i.d.) or three times a day (t.i.d.). This can be increased to 50 mg b.i.d. or t.i.d. after 1 or 2 weeks if the lower dose is ineffective. Doses of captopril higher than 50 mg b.i.d. are recommended only with concomitant administration of a thiazide diuretic.

**Pharmacokinetics**— Following oral administration, approximately 60% to 75% of the dose of captopril is rapidly absorbed from the gastrointestinal tract in fasting healthy adults or hypertensive patients. Peak blood levels of unchanged captopril occur about 1 hour after oral administration. Areas under the concentration-time curve and maximum blood concentrations after single oral doses of captopril appear to be dose-related over a range of 10 to 100 mg. Approximately 25% to 30% of the drug in the systemic circulation is bound to plasma proteins.

Because the presence of food in the GI tract is reported to reduce absorption of the drug by 30% to 40%, captopril is labeled to be dosed 1 hour before meals. Blood pressure reduction is usually maximal 60 to 90 minutes post-dose. The elimination half-life of captopril is reported to be about 2 hours.

About half the absorbed dose of captopril is rapidly metabolized, mainly to captopril-cysteine disulfide and to the disulfide dimer of captopril. Captopril and its metabolites are excreted in the urine. Renal excretion of unchanged captopril occurs via tubular secretion. In patients with normal renal function, more than 95% of the absorbed dose is excreted in the urine in 24 hours. About 40% to 50% of the drug excreted in the urine is unchanged captopril.

**in vivo bioequivalence study<sup>5</sup>**  
Product Information—

1. FDA Designated Reference Product: Capoten® (Squibb) 100-mg tablets.
2. **Batch Size**—The test batch or lot must be manufactured under production conditions and must be of a size at least 10% that of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.
3. **Potency**—The assayed potency of the reference product should not differ from that of the test product by more than 5%.

**Type of Study Required**— A single-dose, randomized, two-period, two-treatment, two-sequence crossover study under fasting conditions comparing 100-mg doses of the test and reference products is required.

**Recommended Protocol for Conducting a Single-Dose Bioequivalence Study Under Fasting Conditions**—

**Objective**— The objective is to compare the rate and extent of absorption of a generic formulation with that of a reference formulation when given as equal labeled doses.

Design—The study design is a single-dose, two-treatment, two-period, two-sequence crossover with a 1-week washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to each of the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

Facilities—The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

Selection of Subjects—The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 24 subjects be used in this study. Subjects should be healthy volunteers aged 18 to 50 years and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of acceptable medical history, physical examination, and clinical laboratory test results. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. Written, informed consent must be obtained from all study participants before they are accepted into the studies.

Procedure—Following an overnight fast of at least 10 hours, subjects should be given a single 100-mg dose of the test or reference product with 240 mL of water. Subject blood pressure and pulse rate should be measured immediately before drug administration (pre-dose) and at 0.5, 1, 1.5, 2, 3, 4, 6, and 8 hours post-dose.

Restrictions—Study volunteers should observe the following restrictions:

- a. Water may be taken except for 1 hour before and after drug administration, when no liquid is allowed other than that needed for drug dosing.
- b. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- c. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- d. Subjects should take no Rx medications, including oral contraceptives, beginning 2 weeks and no OTC medications beginning 1 week before drug administration and until after the study is completed.

Blood Sampling—Venous blood samples should be collected pre-dose (0 hours) and at 0.25, 0.50, 0.75, 1, 1.25, 1.50, 1.75, 2, 2.50, 3, 3.50, 4, 4.50, 5, 6, 7, 8, and 10 hours post-dose. Whole blood or blood plasma may be used for the assay. In either case, the blood samples should be chemically stabilized immediately after collection (see Analytical Methods below).

If plasma is to be assayed, it should be separated promptly from the stabilized whole blood. The whole blood or blood plasma samples should then be immediately frozen until assayed. Following a minimum 1-week washout period, subjects should begin the second phase of the study.

Analytical Methods—Captopril should be measured in an appropriate biological matrix such as whole blood or blood plasma. Several assay methods are available. The method chosen should be fully validated with respect to adequate sensitivity, specificity, linearity, recovery, and accuracy and precision (both within and between days). Because the thiol group of captopril is readily oxidized, a chemical stabilizer must be added to the blood samples immediately after collection. Stability of the samples under frozen storage conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined. Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

Statistical Analysis of Pharmacokinetic Data—See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances.

Clinical Report, Side Effects, and Adverse Reactions—Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions to the study formulations should be reported.

Retention of Samples—The laboratory conducting the bioequivalence testing should retain an appropriately identified reserve sample of both the test and reference products used to perform the in vivo bioequivalence study for approval of the application. Each reserve sample should consist of at least 200 dosage units and should be retained for a period of not less than 5 years following approval of the application. For more information on retention of bioequivalence samples, refer to 21 CFR 320.63.

#### in vitro testing requirements

Dissolution Testing—Conduct dissolution testing on 12 dosage units of the test product versus 12 units of the reference product. The biostudy lots should be used for those product strengths tested in vivo. The current official USP dissolution method (see [Dissolution \(711\)](#)) should be followed and should be referenced by the sponsor. The following method and tolerances are currently recommended for this product:

Medium: 0.1 N hydrochloric acid; 900 mL.

Apparatus 1: 50 rpm.

Times: 10, 20, and 30 minutes.

Procedure—Use USP if available, or other validated method (see [Validation of Compendial Procedures \(1225\)](#)).

Tolerances (Q): not less than 80% in 20 minutes.

The percentage of label claim dissolved at each specified testing interval should be reported for each individual dosage unit. The mean percentage dissolved, the range (highest, lowest) of dissolution, and the coefficient of variation (relative standard deviation) should be reported.

Content Uniformity Test—Content uniformity testing on the test product lots should be performed as described in USP.

#### waiver requirements

Waiver of in vivo bioequivalence study requirements for the 12.5-, 25-, and 50-mg strengths of the generic product may be granted pursuant to 21 CFR 320.22(d)(2), provided the following conditions are met:

1. The lower strengths are proportionally similar in both active and inactive ingredients to the 100-mg strength, which has been demonstrated to be bioequivalent to the reference product in vivo.
2. The 12.5-, 25-, and 50-mg strengths of the generic product meet the dissolution test requirements.

#### Cefaclor Capsules and Suspensions—In Vivo Bioequivalence and In Vitro Dissolution Testing<sup>4</sup>

Clinical Usage/Pharmacology—Cefaclor is a cephalosporin antibiotic that inhibits bacterial cell-wall synthesis in a manner similar to that of penicillin. Cefaclor is used in the treatment of otitis media caused by susceptible *Streptococcus pneumoniae*, *Haemophilus influenzae* (including ampicillin-resistant strains), *staphylococci*, and group A  $\beta$ -hemolytic streptococci; of lower respiratory tract infections (including pneumonia) caused by susceptible *Streptococcus pneumoniae*, *Haemophilus influenzae*, or group A  $\beta$ -hemolytic streptococci; of upper respiratory tract infections (including pharyngitis and tonsillitis) caused by susceptible group A  $\beta$ -hemolytic streptococci; of urinary tract infections (including pyelonephritis and cystitis) caused by susceptible *Escherichia coli*, *Proteus mirabilis*, *Klebsiella*, or *staphylococci*; or of skin and skin structure infections caused by susceptible *Staphylococcus aureus* or group A  $\beta$ -hemolytic streptococci.

The usual adult dosage is 250 mg every 8 hours. For more severe infections (such as pneumonia), doses may be doubled.

Pharmacokinetics—Cefaclor is well absorbed after oral administration to fasting subjects. Total absorption is similar in the fasted and the fed states. When it is taken with food, the peak concentration achieved is 50% to 75% of that observed in fasting subjects and generally appears about 1 hour later.

Following administration of 250-mg, 500-mg, and 1-g doses to fasting subjects, average peak serum levels of approximately 7, 13, and 23  $\mu$ g per mL, respectively, were obtained within 30 to 60 minutes. Approximately 60% to 85% of the drug is excreted unchanged in urine within 8 hours, the major portion being excreted within the first 2 hours. The serum elimination half-life in subjects with normal renal function is 0.6 to 0.9 hour. In patients with severely reduced renal function, the plasma elimination half-life of the drug is 2.3 to 2.8

hours. Hemodialysis shortens the half-life by 25% to 30%.

[in vivo bioequivalence studies<sup>5</sup>](#)

Product Information—

1. FDA Designated Reference Product: Cedlor® (Eli Lilly) 500-mg capsules; or powder for oral suspension containing 375 mg per 5 mL (Eli Lilly).
2. Batch Size—The test batch or lot must be manufactured under production conditions and must be of a size at least 10% that of the largest lot planned for full production or a minimum of 100,000 capsules, whichever is larger.
3. Potency—The assayed potency of the reference product should not differ from that of the test product by more than 5%.

Types of Studies Required—

1. A single-dose, randomized, two-period, two-treatment, two-sequence crossover study under fasting conditions comparing 500-mg doses of the test and reference capsules and 375-mg-per-5-mL doses of the test and reference suspensions is required.
2. A single-dose, randomized, three-treatment, three-period, six-sequence, crossover, limited food effects study comparing equal doses of the test product under fasting conditions as well as the test and reference products when administered immediately following a standard high-fat breakfast<sup>6</sup> is required.

Recommended Protocol for Conducting a Single-Dose Bioequivalence Study under Fasting Conditions—

Objective— The objective is to compare the rate and extent of absorption of a generic formulation with that of a reference formulation when given as equal labeled doses.

Design— The study design is a single-dose, two-treatment, two-period, two-sequence crossover with a 1-week washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

Facilities— The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

Selection of Subjects— The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 24 subjects be used in this study. Subjects should be healthy volunteers aged 18 to 50 years and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of acceptable medical history, physical examination, and clinical laboratory test results. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition, including sensitivity to cephalosporin or penicillin analogues, that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. Written, informed consent must be obtained from all study participants before they are accepted into the study.

Procedure— Following an overnight fast of at least 10 hours, subjects should be administered a single dose of the test or reference product with 240 mL of water.

Restrictions— Study volunteers should observe the following restrictions:

1. Water may be taken except for 1 hour before and after drug administration when no liquid is allowed other than that needed for drug dosing.
2. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
3. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
4. Subjects should take no Rx medications, including oral contraceptives, or OTC medications beginning 2 weeks before drug administration and until after the study is completed.

Blood Sampling— Venous blood samples should be collected pre-dose (0 hours) and at 0.25, 0.50, 0.75, 1.0, 1.25, 1.50, 2, 3, 4, 5, 6, and 8 hours post-dose. Due to the chemical instability of cefaclor, the blood samples should be analyzed as soon as they are drawn, or plasma samples should be promptly frozen at  $-70^{\circ}\text{C}$  until analysis. Following a minimum 1-week washout period, subjects should begin Phase II. For each subject, the sponsor should state the time elapsed between sample collection and its assay. An explanation should be given for any missing samples.

Analytical Methods— For the measurement of cefaclor in plasma samples, a microbiological assay, HPLC method, or other suitable method should be selected. The method used should be described in detail, and references, if any, should be cited. The method should include detailed calculation procedures for the assay results. The method chosen should be fully validated with respect to adequate sensitivity, specificity, linearity, recovery, and accuracy and precision (both within and between days). Stability of the analyte in plasma samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined. It should be noted that cefaclor is most stable in the acid pH range at a temperature of  $4^{\circ}\text{C}$ . For analytical work, cefaclor reference standard stock solutions should be prepared fresh daily in pH 4.5 buffer.

Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

Statistical Analysis of Pharmacokinetic Data— See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances.

Limited Food Effects Study— The limited food effects study should be performed in the same manner as the single-dose study under fasting conditions, with the following exceptions:

Procedure— An equal number of subjects should be assigned to each of the 6 dosing sequences possible in a three-treatment, three-period study design (total 18 subjects). Each subject will receive the following treatments:

TREATMENT 1: Generic product, a 500-mg cefaclor capsule or 375-mg-per-5-mL suspension administered after a standard high-fat breakfast.

TREATMENT 2: Reference product, a 500-mg Cedlor® capsule or 375-mg-per-5-mL suspension (Eli Lilly) administered after a standard high-fat breakfast.

TREATMENT 3: Generic product, a 500-mg cefaclor capsule or 375-mg-per-5-mL suspension administered under fasting conditions.

Following a 10-hour fast, the subjects receiving treatments under fed conditions should be served a standard high-fat breakfast. The subjects should have 30 minutes to finish the entire breakfast, and then should immediately receive Treatment 1 or Treatment 2, taken with 240 mL of water. Subjects receiving the treatment under fasting conditions should be dosed with Treatment 3, taken with 240 mL of water only. The same lots of the test and reference products should be used in the fasted and fed studies. No food should be allowed for at least 4 hours post-dose with water allowed after the first hour. Subjects should be served scheduled standardized meals throughout the study, and the same meals should be served during both phases of the study.

Statistical Analysis— In general, a comparable food effect will be assumed if the AUC<sub>0-T</sub>, AUC<sub>0- $\infty$</sub> , and C<sub>max</sub> mean values for the test product administered under fed conditions are within 20% of the respective mean values obtained for the reference product administered under fed conditions.

Clinical Report, Side Effects, and Adverse Reactions— Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions to the study formulations should be reported.

Retention of Samples— The laboratory conducting the bioequivalence testing should retain an appropriately identified reserve sample of both the test and reference products used to perform the in vivo bioequivalence study for approval of the application. Each reserve sample should consist of at least 200 dosage units and should be retained for a minimum of 5 years following approval of the application. For more information on retention of bioequivalence samples, refer to 21 CFR 320.63.

in vitro testing requirements

Dissolution Testing— Conduct dissolution testing on 12 dosage units of the test product versus 12 units of the reference product. The biostudy lots should be used for those product strengths tested in vivo. The current official USP dissolution method (see [Dissolution](#) 711) should be followed and should be referenced by the sponsor. The following method and tolerances are currently recommended for this product:

Medium: water; 900 mL.

Apparatus 2: 50 rpm.

Times: 10, 20, 30, and 45 minutes.

Procedure— Use USP if available, or other validated method (see [Validation of Compendial Procedures \(1225\)](#)).

Tolerance (Q) not less than 80% in 30 minutes.

The percentage of label claim dissolved at each specified testing interval should be reported for each individual dosage unit. The mean percentage dissolved, the range (highest, lowest) of dissolution, and the coefficient of variation (relative standard deviation) should be reported.

Content Uniformity Test— Content uniformity testing on the test product lots should be performed as described in USP.

waiver requirements

Waiver of in vivo bioequivalence study requirements for the 250-mg strength of the generic capsule may be granted pursuant to 21 CFR 320.22(d)(2), provided the following conditions are met:

1. The 250-mg capsule is proportionally similar in both active and inactive ingredients to the firm's 500-mg capsule, which has been demonstrated to be bioequivalent to the reference product *in vivo*.
2. The 250-mg capsule of the generic product meets dissolution test requirements.

Waiver of in vivo bioequivalence study requirements for the powder for reconstitution as a suspension for oral administration, 125-, 187-, and 250-mg-per-5-mL strengths of the generic product may be granted pursuant to 21 CFR 320.22(d)(2) provided the following conditions are met:

1. The 125-, 187-, and 250-mg-per-5-mL suspensions are proportionally similar in their active and inactive ingredients to the firm's 375-mg-per-5-mL suspension.
2. An acceptable in vivo bioequivalence study has been conducted for the 375-mg-per-5-mL suspension.

#### Cimetidine Tablets—In Vivo Bioequivalence and In Vitro Dissolution Testing<sup>4</sup>

Clinical Usage/Pharmacology— Cimetidine is a histamine H<sub>2</sub>-receptor antagonist, used for the treatment of endoscopically or radiographically confirmed duodenal ulcer, pathologic GI hypersecretory conditions (e.g., Zollinger-Ellison syndrome, systemic mastocytosis, and multiple endocrine adenomas), and active, benign, gastric ulcer.

Cimetidine inhibits competitively and selectively the interaction of histamine with H<sub>2</sub> receptors. It inhibits basal (fasting) and nocturnal acid secretion, acid secretion stimulated by food, sham feeding, fundic distention, and various pharmacological agents.

Effective cimetidine concentrations between 0.5 and 1.0 µg per mL are required to suppress gastric acid secretion under basal or stimulated conditions. However, no correlation to the therapeutic response from pharmacokinetic data has been established between plasma concentrations of cimetidine or any of the pharmacodynamic parameters and duodenal ulcer healing rate.

For treatment of active duodenal ulcer, the usual adult oral dosage of cimetidine is 800 mg daily at bedtime. For maintenance therapy following healing of acute duodenal ulcer, the usual oral dosage of cimetidine is 400 mg daily at bedtime. For the treatment of pathologic hypersecretory conditions, the usual adult oral dosage is 300 mg, 4 times daily with meals and at bedtime. For the treatment of active benign gastric ulcer, the usual adult oral dosage is 800 mg at bedtime or 300 mg, 4 times daily with meals and at bedtime.

Pharmacokinetics— Following intravenous administration, the plasma concentration profile follows multicompartmental characteristics. The total systemic clearance is high (500 to 600 mL per minute) and is mainly determined by renal clearance. The volume of distribution is of the order of 1 L per kg. Elimination half-life is approximately 2 hours. Following oral administration of cimetidine, 2 plasma concentration peaks are frequently observed at about 1 hour and after about 3 hours, probably due to discontinuous absorption in the intestine or individual variation in gastric emptying (but not enterohepatic recycling since the biliary excretion rate in humans is less than 2%). The absolute bioavailability is about 60% in healthy subjects and around 70% in peptic ulcer patients. Absorption and clearance of cimetidine are linear after 200- and 800-mg doses. When given with food, the extent of absorption of the drug remains unchanged, but the time to reach the maximum peak concentration is delayed with only 1 peak in the plasma concentration curve observed at about 2 hours following dosing. Plasma protein binding of cimetidine is 20% and does not significantly affect the pharmacokinetics of the drug. Cimetidine distributes extensively into the kidney, lung, and muscle tissue but less than 1% into the cerebrospinal fluid.

Following IV administration, about 50% to 80% of the dose is recovered in urine as unchanged cimetidine. This fraction is less after oral doses. Approximately 2% of cimetidine is excreted in the bile. About 25% to 40% of the cimetidine dose is eliminated as metabolites, formed mainly in the liver. The metabolites are sulfoxide and 5-hydroxymethyl derivatives, and possibly guanylurea, although this latter compound may result from in vitro degradation. Elimination of cimetidine is accelerated in the presence of phenobarbital due to induction of its metabolism. Clearance of the drug is higher in children, who have greater renal elimination rates. With increasing age, the volume of distribution of the drug decreases, total plasma clearance decreases as a function of decreasing renal clearance, and plasma half-life increases.

#### in vivo bioequivalence studies<sup>5</sup>

##### Product Information—

1. FDA Designated Reference Product: Tagamet® (SmithKline Beecham) 800-mg tablets.
2. Batch Size—The test batch or lot must be manufactured under production conditions and must be of a size that is at least 10% of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.
3. Potency—The assayed potency of the reference product should not differ from that of the test product by more than 5%.

#### Types of Studies Required—

1. A single-dose, randomized, fasting, two-period, two-treatment, two-sequence crossover study comparing the 800-mg strength of the test and reference products. This protocol may also be used for lower strength tablets if an 800-mg tablet is not being manufactured. In this case, equal doses of the test and reference products should be used.
2. A single-dose, two-way crossover, full food study comparing the 800-mg strength of the test and reference products. Due to the double-peak phenomenon, which is only observed under fasting conditions, the food study may be more reliable for determining the bioequivalency of the test product and therefore should be done with a full complement of subjects. This protocol may also be used for lower strength tablets if an 800-mg tablet is not being manufactured. In this case, equal doses of the test and reference products should be used.

#### Recommended Protocol for Conducting a Single-Dose Bioequivalence Study under Fasting Conditions—

Objective— The objective is to compare the rate and extent of absorption of a generic formulation with that of a reference formulation when given as equal labeled doses.

Design— The study design is a single-dose, two-treatment, two-period, two-sequence crossover with a 1-week washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

Facilities— The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

Selection of Subjects— The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 24 subjects be used in this study. Subjects should be healthy volunteers aged 18 to 50 years and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of acceptable medical history, physical examination, and clinical laboratory

test results. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. Written, informed consent must be obtained from all study participants before they are accepted into the study.

Procedure— Following an overnight fast of at least 10 hours, subjects should be administered a single 800-mg dose of the test or reference product with 240 mL of water.

Restrictions— Study volunteers should observe the following restrictions:

- a. Water may be taken except for 1 hour before and after drug administration, when no liquid is allowed other than that needed for drug dosing.
- b. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- c. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- d. Subjects should take no Rx medications, including oral contraceptives, or OTC medications beginning 2 weeks before drug administration until after the study is completed.

Blood Sampling— Venous blood samples should be collected pre-dose (0 hours) and at 0.25, 0.50, 0.75, 1.0, 1.50, 2.0, 2.50, 3.0, 3.50, 4.0, 5.0, 6.0, 8.0, 10, 12, 16, 20, and 24 hours post-dose. Plasma should be separated promptly and immediately frozen until assayed. Following at least a minimum 1-week washout period, subjects should begin the second phase of the study.

Analytical Methods— Cimetidine should be assayed using a suitable method fully validated with respect to adequate sensitivity, specificity, linearity, recovery, accuracy, and precision (both within and between days). Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined.

Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

Statistical Analysis of Pharmacokinetic Data: See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances.

Clinical Report, Side Effects, and Adverse Reactions— Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions to the study formulations should be reported.

Retention of Samples— The laboratory conducting the bioequivalence testing should retain an appropriately identified reserve sample of both the test and reference products used to perform the in vivo bioequivalence study for approval of the application. Each reserve sample should consist of at least 200 dosage units and should be retained for a period of not less than 5 years following approval of the application. For more information on retention of bioequivalence samples, refer to 21 CFR 320.63.

Recommended Protocol for Conducting a Single-Dose Bioequivalence Study Under Postprandial Conditions— There should be at least 24 healthy volunteers. The postprandial study should be conducted in the same manner as described for the fasting study except under fed conditions. The subjects should be given a standard high-fat breakfast<sup>6</sup> after an overnight fast of approximately 10 hours. The dose should be given with 240 mL of water approximately 30 minutes after beginning breakfast. The plasma cimetidine data should be obtained and analyzed in the same manner as described for the fasting study. Due to the double-peal phenomenon, which is only observed under fasting conditions, the postprandial study may be more reliable for determining the bioequivalency of a test product.

#### in vitro testing requirements

Dissolution Testing— Conduct dissolution testing on 12 dosage units of the test product versus 12 units of the reference product. The biostudy lots should be used for those product strengths tested in vivo. The current official USP dissolution method (see [Dissolution](#) 711) should be followed and should be referenced by the sponsor. The following method and tolerances are currently recommended for this product:

Medium: deaerated water; 900 mL.

Apparatus 1: 100 rpm.

Times: 10, 15, and 30 minutes.

Procedure— Use USP if available, or other validated method (see [Validation of Compendial Procedures](#) 1225).

Tolerances (Q): not less than 75% in 15 minutes.

The percentage of label claim dissolved at each specified testing interval should be reported for each individual dosage unit. The mean percentage dissolved, the range (highest, lowest) of dissolution, and the coefficient of variation (relative standard deviation) should be reported.

Content Uniformity Test— Content uniformity testing on the test product lots should be performed as described in USP.

#### waiver requirements

Waiver of in vivo bioequivalence study requirements for the 200-, 300-, and 400-mg strengths of the generic product may be granted pursuant to 21 CFR 320.22(d)(2), provided the following conditions are met:

1. The 200-, 300-, and 400-mg strengths are proportionally similar in both active and inactive ingredients to another strength (800 mg), which has been demonstrated to be bioequivalent to a reference (800 mg) product in vivo.
2. The 200-, 300-, and 400-mg strengths of the generic product meet all applicable compendial requirements, including the specified dissolution and content uniformity testing requirements.
3. The drug product follows linear kinetics over its range of available strengths.

#### Diclofenac Sodium Delayed-Release Tablets—In Vivo Bioequivalence and In Vitro Dissolution Testing<sup>4</sup>

Clinical Usage/Pharmacology— Diclofenac sodium is an orally administered nonsteroidal anti-inflammatory drug (NSAID), which also has analgesic and antipyretic properties. Currently approved indications for diclofenac sodium are for the acute or chronic treatment of the signs and symptoms of rheumatoid arthritis (RA), osteoarthritis, and ankylosing spondylitis. Doses above 200 mg a day in 3 or 4 divided doses have not been studied in RA patients. Diclofenac sodium inhibits prostaglandin synthesis, which may be involved in its mechanism of action. Due to possible cross-reactivity, diclofenac sodium is contraindicated in patients in whom aspirin or other NSAID has produced asthma, urticaria, or allergic reactions.

Pharmacokinetics— Diclofenac sodium is rapidly absorbed following oral administration with reported time of maximum concentration (Tmax) mean values of 1 to 3 hours and ranges of 1 to 5 hours under fasting conditions in normal volunteers. After single oral doses of 25-, 50-, and 75-mg delayed-release tablets, reported maximum concentrations (Cmax) in normal fasting subjects were 0.5 to 1, 0.9 to 1.5, and 1.9 to 2  $\mu$ g per mL, respectively. Area under the plasma concentration-time curve (AUC) increases linearly over the dose range 25 to 150 mg; however, Cmax is less than dose-proportional with values of 1, 1.5, and 2  $\mu$ g per mL after doses of 25, 50, and 75 mg, respectively.

Diclofenac sodium undergoes first-pass metabolism to give a systemic availability of 50% to 60%. Food may markedly delay the rate of absorption from delayed-release tablets but does not appear to change AUC significantly. In two single-dose (50 mg) studies, the nonfasting mean Tmax values were 5.4 hours (N = 12, range 2.5 to 12 hours) and 9.7 hours (N = 6, range 8 to 10 hours). The volume of distribution (Vd) of diclofenac sodium is about 0.12 to 0.17 L per kg and it is greater than 99% bound to plasma proteins. After an IV dose, elimination of diclofenac sodium from plasma appears triphasic; after oral dosing, reported terminal  $\beta$ -phase half-life ( $t_{1/2}$ ) values are 1 to 2 hours with a range of 0.5 to 4.3 hours. The apparent elimination  $t_{1/2}$  of total radiolabeled compounds in patients with normal renal function is 25 to 33 hours.

The major route of elimination is hepatic clearance with 90% of a dose eliminated in 96 hours with about 65% of the dose in urine and 35% of the dose in bile. The dose is excreted as glucuronide and sulfate conjugates of unchanged drug and four metabolites. The principal metabolite (4'-hydroxy) has about 1/40 the activity of the parent drug in animal models of arthritis. It is possible that this metabolite may contribute to the overall activity because it accounts for 30% to 40% of the dose.

#### in vivo bioequivalence studies<sup>5</sup>

## Product Information—

FDA Designated Reference Product: Voltaren® (Geigy) 75-, 50-, or 25-mg delayed-release oral tablets.

Batch Size— The test batch or lot must be manufactured under production conditions and must be of a size that is at least 10% that of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.

Potency— The assayed potency of the reference product should not differ from that of the test product by more than 5%.

## Types of Studies Required—

1. A single-dose, randomized, two-period, two-treatment, two-sequence crossover study under fasting conditions comparing equal doses of the test and reference products.
2. A single-dose, randomized, three-treatment, three-period, six-sequence crossover, limited food effects study comparing equal doses of the test and reference products when administered immediately following a standard high-fat breakfast.<sup>6</sup>
3. As stated in 21 CFR 320.22(d)(2)(iv), no waiver may be granted for the 25- or 50-mg strengths based on the 75-mg strength. Separate fasting studies must be performed for all of the strengths.

## Recommended Protocol for Conducting a Single-Dose, Fasted Bioequivalence Study—

Objective— The objective is to compare the rate and extent of absorption of a generic formulation with that of a reference formulation when given as equal labeled doses.

Design— The study design is a single-dose, two-treatment, two-period, two-sequence crossover with a 2-week washout period between phases. An equal number of subjects should be randomly assigned to the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

Facilities— The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

Selection of Subjects— The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 36 subjects be used in this study. Subjects should be healthy, preferably nonsmoking, volunteers aged 18 to 50 years and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of acceptable medical history, physical examination, and clinical laboratory test results. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. If smokers are included, they should be identified as such. Written, informed consent must be obtained from all study participants before they are accepted into the study.

Procedure— Following an overnight fast of at least 10 hours, subjects should be administered a single dose of the test or reference product with 240 mL of water.

## Restrictions— Study volunteers should observe the following restrictions:

- a. Water may be taken except for 1 hour before and after drug administration when no liquid is allowed other than that needed for drug dosing.
- b. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- c. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- d. Subjects should take no Rx medication, including oral contraceptives, or OTC medication beginning 1 week before drug administration and until after the study is completed.

Blood Sampling— Venous blood samples should be collected pre-dose (0 hours) and at 0.50, 0.75, 1, 1.25, 1.50, 1.75, 2, 2.25, 2.50, 2.75, 3, 3.33, 3.67, 4, 5, 6, 8, 10, and 12 hours post-dose. Plasma serum should be separated promptly and immediately frozen until assayed. Following a 2-week washout period, subjects should begin the second phase of the study.

Analytical Methods— The active ingredient should be assayed using a suitable method fully validated with respect to adequate sensitivity, specificity, linearity, recovery, accuracy, and precision (both within and between days). Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined. Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

Subject Monitoring— Blood pressure and pulse rate should be monitored hourly during the first 4 hours of the study. Any subject with a heart rate less than 45 bpm or greater than 110 bpm should have an electrocardiogram (lead II) performed and have their pulse monitored hourly. Subjects should report any unusual symptoms observed during the study. Subjects should be periodically questioned during each phase of the study for any unusual symptoms experienced after drug administration.

Statistical Analysis of Pharmacokinetic Data— See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances. In addition, the following parameters should be tabulated: lag time (Tlag), the time of the last zero concentration before the first non-zero concentration; and adjusted Tmax (Tmaxadj), which is the observed Tmax minus Tlag.

## Limited Food Effects Study—

Objective— The objective is to compare the rate and extent of absorption of diclofenac sodium from a generic formulation with that from a reference formulation under nonfasting conditions, and to compare the rate and extent of absorption of the drug form from a generic product under fasting and nonfasting conditions when given as equal labeled doses.

Design— The study design is a single-dose, three-treatment, three-period, six-sequence crossover with a 2-week washout period between Phase I and Phase II, and Phase II and Phase III of dosing.

In view of the wide range of reported values for Tmax in the presence of food, it is recommended that the sponsor perform a pilot study to determine appropriate sampling times for the limited food effects study.

The limited food effects study (12 to 18 subjects) should be performed in the same manner as the single-dose fasting study, with the following exceptions:

Procedure— An equal number of subjects should be assigned to each of the 6 dosing sequences possible in a three-treatment, three-period study design. Each subject will receive the following treatments:

TREATMENT 1: Generic product, a 75-mg tablet, administered after a standard high-fat breakfast.

TREATMENT 2: Reference product, a 75-mg Voltaren® tablet, administered after a standard high-fat breakfast.

TREATMENT 3: Generic product, a 75-mg tablet, administered under fasting conditions.

Following a 10-hour fast, the subjects receiving treatments under fed conditions should be served a standard high-fat breakfast. The subjects should have 30 minutes to finish the entire breakfast, and then should immediately receive Treatment 1 or Treatment 2, with 240 mL of water. Subjects receiving the treatment under fasting conditions should receive Treatment 3, with 240 mL of water. The same lots of the test and reference products should be used in the fasted and fed studies. No food should be allowed for at least 4 hours post-dose, with water allowed after the first hour. Subjects should be served scheduled standardized meals throughout the study, and the same meals should be served during all phases of the study.

Statistical Analysis— In general, a comparable food effect will be assumed if the AUC0- $\infty$ , AUC0- $\infty$ , and Cmax mean values for the test product administered under fed conditions are within 20% of the respective mean values for the reference product administered under fed conditions.

Clinical Report, Side Effects, and Adverse Reactions— Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions to the study formulations should be reported.

Retention of Samples— The laboratory conducting the bioequivalence testing should retain appropriately identified reserve samples of both the test and reference products used to perform the in vivo bioequivalence studies for approval of the application. Each reserve sample should consist of at least 200 dosage units, and should be retained for a minimum of 5 years following approval of the application. For more information on retention of bioequivalence samples, refer to 21 CFR 320.63.

#### in vitro testing requirements

There is currently no official USP dissolution method for a diclofenac sodium dosage form. A tentative method recommended by FDA is described below.

**Drug Release Testing**— Conduct dissolution testing on 12 dosage units of the test product and the reference product, employing the biostudy lots. The following method and tolerances are currently recommended for this product:

##### Method B (724) —

Medium: 2 hours in 0.1 N hydrochloric acid followed by 45 minutes in pH 6.8, 0.05 M phosphate buffer prepared as follows. Dissolve 76 g of tribasic sodium phosphate in water to obtain 1000 mL of solution. Mix 250 mL of this solution with 750 mL of 0.1 N hydrochloric acid and, if necessary, adjust with 2 N hydrochloric acid or 2 N sodium hydroxide to a pH of  $6.8 \pm 0.05$ ; 900 mL.

Apparatus 2: 50 rpm.

Times: acid stage: 30, 60, and 120 minutes; buffer stage: 5, 10, 20, 30, 45, and 60 minutes.

Procedure— Use USP if available, or other validated method (see [Validation of Compendial Procedures \(1225\)](#)).

Tolerances (Q): acid stage: not more than 10% in 120 minutes; buffer stage: not less than 75% in 45 minutes.

The percentage of label claim dissolved at each specified testing interval should be reported for each individual dosage unit. The mean percentage dissolved, the range (highest, lowest) of dissolution, and the coefficient of variation (relative standard deviation) should be reported.

**Content Uniformity Test**— Content uniformity testing on the test product lots should be performed as described in USP.

##### waiver requirements

As stated in 21 CFR 320.22(d)(2)(iv), no waiver may be granted for the 25- or 50-mg strengths based on the 75-mg strength. Separate studies must be performed for all of the strengths.

The limited food effects study requirement for the 50- and 25-mg strengths of the generic diclofenac sodium product may be waived if the following conditions are met:

1. The limited food study for the 75-mg strength demonstrates bioequivalence to the reference product.
2. The formulations for the 50- and 25-mg strengths are proportionally similar to the 75-mg strength.

#### Diltiazem Hydrochloride Tablets—In Vivo Bioequivalence and In Vitro Dissolution Testing<sup>4</sup>

**Clinical Pharmacology/Usage**— Diltiazem hydrochloride is classified as a cardiovascular preparation and an anti-anginal calcium channel blocker. It is currently approved for angina pectoris due to coronary artery spasm and for chronic stable angina (classic effort-associated angina). Its therapeutic effects are brought about by its ability to block calcium entry into cardiac and vascular smooth muscle cells. It is known to dilate coronary arteries as well as to increase the tolerance of angina sufferers to physical exertion by reducing the demand for myocardial oxygen.

The dosage is adjusted according to the needs of adult patients. The starting regimen of 30 mg four times daily is increased gradually until the optimum response is achieved with safety. Safety and efficacy of diltiazem is not established for pediatric use. Diltiazem is prescribed to a pregnant woman only if the potential benefit justifies any potential risk to the fetus. A nursing mother taking diltiazem should not breast-feed her infant. The most commonly observed adverse reactions are edema, headache, nausea, dizziness, rash, and asthenia (weakness, lethargy).

**Pharmacokinetics**— After oral administration of diltiazem, 80% to 90% of the dose is absorbed. Diltiazem undergoes extensive first-pass metabolism and has 40% to 44% oral bioavailability. Diltiazem is 70% to 80% bound to plasma proteins. The peak plasma diltiazem level is reached within 2 to 3 hours after a single oral dose. Elimination half-lives of 3 to 5 hours and 5 to 9 hours have been reported for diltiazem. Diltiazem is metabolized by three major pathways into various metabolites. These pathways are O-deacetylation, N-demethylation, and O-demethylation. Desacetyl diltiazem (DAD) and N-monodemethyl diltiazem (NMD) are active metabolites.

Until 1987, the measurement of DAD and NMD was found to be difficult in single-dose (IV and oral) studies. In 1989, however, Boyd et al. showed the possibility of measuring DAD and NMD following a single oral dose.

At one time, DAD was thought to be the major metabolite of diltiazem. It is 40% to 50% active compared to the parent compound and shows, on average, only 20% of the plasma levels produced by diltiazem. DAD is 68% bound to plasma proteins. Following a single oral dose, average half-lives of 7.5 hours and 19.5 hours have been reported.

Recent studies have demonstrated that N-monodemethylation, leading to the formation of NMD, which is less active than DAD, is the major metabolic pathway. Average plasma levels of NMD are about 40% of those of diltiazem. NMD is 77% bound to plasma proteins and has an average half-life of 8 to 10 hours.

Diltiazem hydrochloride has a therapeutic concentration range of 50 to 200 ng per mL and is toxic above 1200 ng per mL.

##### in vivo bioequivalence studies<sup>5</sup>

##### Product Information—

FDA Designated Reference Product: Cardizem® (Marion) 120-mg tablets.

**Batch Size**— The test batch or lot must be manufactured under production conditions and must be of a size at least 10% that of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.

**Potency**— The assayed potency of the reference product should not differ from that of the test product by more than 5%.

**Type of Study Required**— A single-dose, randomized, two-period, two-treatment, two-sequence crossover study under fasting conditions comparing equal doses of the test and reference products.

##### Recommended Protocol for Conducting a Single-Dose, Fasted Bioequivalence Study—

**Objective**— The objective is to compare the rate and extent of absorption of diltiazem hydrochloride from a generic formulation with that from a reference formulation when given as equal labeled doses.

**Design**— The study design is a single-dose, two-treatment, two-period, two-sequence crossover with a 1-week washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to each of the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

**Facilities**— The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

**Selection of Subjects**— The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 24 subjects be used in this study. Subjects should be healthy, preferably nonsmoking, volunteers aged 18 to 55 and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of acceptable medical history, physical examination, and clinical laboratory test results. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. If smokers are included, they should be identified as such. Written, informed consent must be obtained from all study participants before they are accepted into the study.

**Procedure**— Following an overnight fast of at least 10 hours, subjects should be administered a single 120-mg dose of the test or reference product with 240 mL of water.

Restrictions— Study volunteers should observe the following restrictions:

- a. Water may be taken except for 1 hour before and after drug administration when no liquid is allowed other than that needed for drug dosing.
- b. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- c. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- d. Subjects should take no Rx medications, including oral contraceptives, beginning 2 weeks and no OTC medications beginning 1 week before drug administration and until after the study is completed.

Blood Sampling— Venous blood samples should be collected pre-dose (0 hours) and at 0.5, 1, 1.5, 2, 3, 4, 6, 8, 10, 12, 14, 16, 24, 30, 36, and 48 hours post-dose. Plasma should be separated promptly and immediately frozen until assayed. Following a minimum 1-week washout period, subjects should begin the second phase of the study.

Subject Monitoring— Blood pressure and pulse rate should be monitored hourly during the first 4 hours of the study. Subjects with a heart rate less than 45 bpm or greater than 110 bpm should have an electrocardiogram (lead II) performed and have their pulse monitored hourly. Subjects should report any unusual symptoms observed during the study. Subjects should be periodically questioned during each phase of the study for any unusual symptoms experienced after drug administration.

Analytical Methods— Diltiazem and its major metabolites, DAD and NMD, should be assayed using a suitable method fully validated with respect to adequate sensitivity, specificity, linearity, recovery, accuracy, and precision (both within and between days). Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined. Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

Statistical Analysis of Pharmacokinetic Data— See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances.

Clinical Report, Side Effects, and Adverse Reactions— Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions and side effects to the study formulations should be reported.

Retention of Samples— The laboratory conducting the bioequivalence testing should retain appropriately identified reserve samples of both the test and reference products used to perform the *in vivo* bioequivalence studies for approval of the application. Each reserve sample should consist of at least 200 dosage units or 5 times the amount needed for complete release testing, whichever is greater, and should be retained for a minimum of 5 years following approval of the application. For more information on retention of bioequivalence samples refer to 21 CFR 320.63.

#### in vitro testing requirements

Dissolution Testing— Conduct dissolution testing on 12 dosage units of the test and reference products, employing the biostudy lots. The current official USP dissolution method (see [Dissolution \(711\)](#)) should be followed and should be referenced by the sponsor. The following times should be used to determine the dissolution profile:  
Times: 30, 60, 90, and 180 minutes.

The percentage of label claim dissolved at each specified testing interval should be reported for each individual dosage unit. The mean percentage dissolved, the range of dissolution (highest, lowest), and the coefficient of variation (relative standard deviation) should be reported.

Content Uniformity Test— Content uniformity testing on the test and reference product lots should be performed as described in USP.

#### waiver requirements

Waiver of *in vivo* bioequivalence study requirements for the immediate-release 30-, 60-, and 90-mg strength of the generic product may be granted pursuant to 21 CFR 320.22(d)(2) provided the following conditions are met:

1. The 30-, 60-, and 90-mg tablets are proportionally similar in both active and inactive ingredients to the firm's 120-mg tablet, which has been demonstrated to be bioequivalent to the reference product *in vivo*.
2. The 30-, 60-, and 90-mg tablets of the generic product meet dissolution test requirements.

#### Flurbiprofen Tablets—*In Vivo* Bioequivalence and *In Vitro* Dissolution Testing<sup>4</sup>

Clinical Usage/Pharmacology— Flurbiprofen is an orally administered nonsteroidal anti-inflammatory drug (NSAID) that also has analgesic and antipyretic properties. Labeled indications for flurbiprofen are for the acute or long-term treatment of the signs and symptoms of rheumatoid arthritis and osteoarthritis. Doses above 300 mg per day are not recommended. Flurbiprofen inhibits prostaglandin synthesis, which may be associated with its mechanism of action. Due to possible cross-reactivity, flurbiprofen is contraindicated in patients in whom aspirin or other NSAIDs have produced asthma, urticaria, or other allergic reactions.

Pharmacokinetics— Flurbiprofen is rapidly absorbed following oral administration, with reported time of maximum concentration values (T<sub>max</sub>) of 1 to 2 hours and ranges of 0.5 to 4 hours. After single oral doses of 50 and 100 mg, reported maximum concentrations (C<sub>max</sub>) in normal subjects were 5.7 to 7.4 µg per mL and 12.6 to 17.2 µg per mL, respectively.

Food may decrease C<sub>max</sub> by 27% to 32% by delaying absorption but does not significantly change area under the plasma concentration-time curve (AUC). In another study, flurbiprofen absorption was found to be bimodal (with double peaks in some cases) after administration of the tablet form in the fasted (water) or fed (apple juice) state. In this study, the lag time before the onset of the second absorption phase was dependent on the gastric emptying time. The volume of distribution (V<sub>d</sub>) of flurbiprofen is about 0.1 L per kg with values of V<sub>d</sub>/F (F = oral availability) of 7.0 to 9.1 L after a 100-mg dose. Flurbiprofen is ≥ 99% bound to plasma proteins (albumin). The binding has been reported to be minimally nonlinear over the concentration ranges encountered clinically. In one study, however, AUC<sub>0-∞</sub> increased linearly over the dose range of 100 to 300 mg. Flurbiprofen elimination from plasma appears biphasic, with terminal  $\beta$ -phase half-life (t<sub>1/2</sub>) values reported from 3 to 7 hours (mean = 5.7 hr; range 3 to 12 hours). The major route of elimination is hepatic clearance, with 95% of a daily dose excreted in urine in 24 hours, either as unchanged drug (20% to 25% of dose) or as the three metabolites—4'-hydroxy (40% to 47%), 3'-hydroxy-4'-methoxy (20% to 30%), and 3',4'-dihydroxy (5%). Other studies have reported 73% to 77% dose recovery in the urine up to 48 hours. Between 60% to 90% of flurbiprofen and its metabolites are present in urine as glucuronide and sulfate conjugates. The 4'-hydroxy metabolite demonstrates low pharmacological activity in animal models.

Virtually all of the anti-inflammatory activity of flurbiprofen is present in the S(+)-enantiomer. Following oral doses of either the pure R(-)- or S(+)-enantiomer, only the administered enantiomer was detectable in plasma or urine. The available evidence from human studies indicates that R-flurbiprofen does not undergo the *in vivo* irreversible inversion to the S-enantiomer that has been observed with other NSAIDs of the 2-arylpropionic acid class. In three studies, significant differences were noted between the enantiomers for AUC with lower values for the R-enantiomer and with increased CL/F (CL = clearance) or decreased t<sub>1/2</sub> for the R-enantiomer.

#### in vivo bioequivalence studies<sup>5</sup>

##### Product Information—

FDA Designated Reference Product: *Ansaid®* (Upjohn) 100-mg tablets.

Batch Size— The test batch or lot must be manufactured under production conditions and must be of a size at least 10% that of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.

Potency— The assayed potency of the reference product should not differ from that of the test product by more than 5%.

#### Types of Studies Required—

1. A single-dose, randomized, two-period, two-treatment, two-sequence crossover study under fasting conditions comparing equal doses of the test and reference products.
2. A single-dose, randomized, three-treatment, three-period, six-sequence crossover, limited food effects study comparing equal doses of the test and reference products when administered immediately following a standard high-fat breakfast.<sup>6</sup>

Recommended Protocol for Conducting a Single-Dose Bioequivalence Study under Fasting Conditions—

Objective— The objective is to compare the rate and extent of absorption of flurbiprofen from a generic formulation with that from a reference formulation when given as equal labeled doses.

Design— The study design is a single-dose, two-treatment, two-period, two-sequence crossover with a 1-week washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to each of the two possible dosing sequences. Before the study begins, the proposed protocols should be approved by an institutional review board.

Facilities— The clinical and analytical laboratories used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

Selection of Subjects— The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 24 subjects should be used in this study. Subjects should be healthy, preferably nonsmoking, volunteers aged 18 to 55 years and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of acceptable medical history, physical examination, and clinical laboratory test results. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. If smokers are included, they should be identified as such. Written, informed consent must be obtained from all study participants before they are accepted into the study.

Procedure— Following an overnight fast of at least 10 hours, subjects should be administered a single dose of the test product or the reference product with 240 mL of water.

Restrictions— Study volunteers should be subject to the following restrictions:

- a. Water may be taken, except for 1 hour before and after drug administration, when no liquid is allowed other than that needed for drug dosing.
- b. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- c. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- d. Subjects should take no Rx medications, including oral contraceptives, beginning 2 weeks and no OTC medications beginning 1 week before drug administration and until after the study is completed.

Blood Sampling— Venous blood samples should be collected at pre-dose (0 hr), and at 0.25, 0.5, 0.75, 1, 1.5, 2, 2.5, 3, 3.5, 4, 5, 6, 8, 10, 12, 18, 24, and 36 hours post-dose. Plasma should be separated promptly and immediately frozen until assayed. Following a minimum 1-week washout period, subjects should begin the second phase of the study.

Subject Monitoring— Blood pressure and pulse rate should be monitored hourly during the first 4 hours of the study. Subjects with a heart rate less than 45 bpm or greater than 110 bpm should have an electrocardiogram (lead II) performed and have their pulse monitored hourly. Subjects should report any unusual symptoms observed during the study. Subjects should be periodically questioned during each phase of the study for any unusual symptoms experienced after drug administration.

Analytical Methods— Flurbiprofen should be assayed using a suitable method fully validated with respect to adequate sensitivity, specificity, linearity, recovery, and accuracy and precision (both within and between days). Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined. Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

Statistical Analysis of Pharmacokinetic Data (Blood Plasma/Serum)— See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances.

#### Limited Food Effects Study—

Objective— The objective is to compare the rate and extent of absorption of flurbiprofen from a generic formulation with that from a reference formulation under nonfasting conditions and to compare the rate and extent of absorption of the drug from a generic formulation under fasting and nonfasting conditions when given as equal labeled doses.

Design— The study design is a single-dose, three-treatment, three-period, six-sequence crossover with a 1-week washout period between Phase I and II, and Phases II and III. An equal number of subjects should be assigned to each of the 6 dosing sequences.

The limited food effects study should be performed in the same manner as the single-dose study under fasting conditions, with the following exceptions:

Procedures— An equal number of subjects should be assigned to each of the 6 dosing sequences possible in a three-treatment, three-period study design (minimum of 12 subjects).

Each subject will receive the following treatments:

TREATMENT 1: Generic product, a 100-mg tablet, administered after a standard high-fat breakfast.

TREATMENT 2: Reference product, a 100-mg Ansaid® tablet (Upjohn), administered after a standard high-fat breakfast.

TREATMENT 3: Generic product, a 100-mg tablet, administered under fasting conditions.

Following a 10-hour fast, the subjects receiving treatments under fed conditions should be served a standard high-fat breakfast. The subjects should have 30 minutes to finish the entire breakfast and then should immediately receive Treatment 1 or Treatment 2, taken with 240 mL of water. Subjects receiving the treatment under fasting conditions should receive Treatment 3, taken with 240 mL of water only. The same lots of the test and reference products should be used as in the fasted and fed studies. No food should be allowed for at least 4 hours post-dose, with water allowed after the first hour. Subjects should be served scheduled standardized meals throughout the study, and the same meals should be served during all phases of the study.

Statistical Analysis— In general, a comparable food effect will be assumed provided the AUC<sub>0-t</sub>, AUC<sub>0-∞</sub>, and C<sub>max</sub> mean values for the test product administered under fed conditions are within 20% of the respective mean values obtained for the reference product administered under fed conditions.

Clinical Report, Side Effects, and Adverse Reactions— Subject medical histories, physical examination reports, and all incidents of possible adverse reactions to the study formulations should be reported.

Retention of Samples— The laboratory conducting the bioequivalence testing should retain appropriately identified reserve samples of both the test and reference products used to perform the in vivo bioequivalence studies for approval of the application. Each reserve sample should consist of at least 200 dosage units or 5 times the amount needed for complete release testing, whichever is greater, and should be retained for a minimum of 5 years following approval of the application. For more information on retention of bioequivalence samples, refer to 21 CFR 320.63.

#### in vitro testing requirements

Dissolution Testing— Conduct dissolution testing on 12 dosage units of the test and reference products, employing the biostudy lots. The current official USP dissolution method in the monograph (see [Dissolution 711](#)) should be followed and should be referenced by the sponsor. The following times should be used to determine the dissolution profile: Times: 10, 20, 30, and 45 minutes.

The percentage of label claim dissolved at each specified testing interval should be reported for each individual dosage unit. The mean percentage dissolved, the range of dissolution (highest, lowest), and the coefficient of variation (relative standard deviation) should be reported.

Content Uniformity Test— Content uniformity testing on the test and reference product lots should be performed as described in USP.

#### waiver requirements

Waiver of in vivo bioequivalence study requirements for the 50-mg strength of the generic tablet may be granted pursuant to 21 CFR 320.22(d)(2) provided the following conditions are met:

1. The 50-mg tablet is proportionally similar in both active and inactive ingredients to the firm's 100-mg tablet, which has been demonstrated to be bioequivalent to the reference product.

2. The 50-mg tablet of the generic product meets dissolution test requirements.

#### Gemfibrozil Capsules and Tablets—In Vivo Bioequivalence and In Vitro Dissolution Testing<sup>4</sup>

**Clinical Pharmacology/Usage—** Gemfibrozil is used clinically as a lipid-regulatory agent, which lowers serum triglycerides and produces a variable reduction in total serum cholesterol.

The decrease occurs primarily in the very low-density lipoprotein (VLDL) and less frequently in the low-density lipoprotein (LDL). In addition, there is elevation of the high-density lipoprotein (HDL) concentration. Gemfibrozil is used in adult patients with all types of dyslipidemia (except type 1). The recommended dosage of gemfibrozil is 600 mg twice daily given 30 minutes before morning and evening meals.

The mechanism whereby gemfibrozil lowers plasma triglycerides and increases HDL cholesterol concentration is not well established. One mechanism by which the drug reduces circulating triglyceride concentration may be through suppression of free fatty acid mobilization from adipose tissue. Gemfibrozil also stimulates lipoprotein lipase activity.

**Gemfibrozil is not recommended for use in patients with hepatic or severe renal dysfunction, including primary biliary cirrhosis and pre-existing gallbladder disease. The main adverse reactions are dyspepsia and abdominal pain.** Gemfibrozil is metabolized to a number of compounds in humans. All the metabolites and the unchanged drug form glucuronide conjugates, which are excreted in urine. The metabolites have no lipid lowering activity.

**Pharmacokinetics—** Following oral administration of gemfibrozil, absorption is rapid and complete. After the administration of gemfibrozil (600 mg twice daily), mean peak plasma concentrations are about 10 to 15 µg per mL. Peak plasma concentrations are attained 1 to 2 hours after administration of single doses up to 2000 mg or after repeated doses up to 800 mg twice daily. Plasma drug concentration is directly proportional to dose and tends to rise during repeated administration, although steady state is achieved within 7 to 14 days with twice daily doses. The mean elimination half-life of gemfibrozil is 1.5 to 3.0 hours.

#### in vivo bioequivalence studies<sup>5</sup>

##### Product Information—

FDA Designated Reference Product: Lopid® (Parke-Davis Co.) 300-mg capsules and 600-mg tablets.

**Batch Size—** The test batch or lot must be manufactured under production conditions and must be of a size that is at least 10% that of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.

**Potency—** The assayed potency of the reference product should not differ from that of the test product by more than 5%.

**Type of Study Required—** A single-dose, randomized, two-period, two-treatment, two-sequence crossover study under fasting conditions comparing equal doses of the test and reference products.

#### Recommended Protocol for Conducting a Single-Dose, Fasted Bioequivalence Study—

**Objective—** The objective is to compare the rate and extent of absorption of a generic formulation with that of a reference formulation when given as equal labeled doses.

**Design—** The study design is a single-dose, two-treatment, two-period, two-sequence crossover with a 2-week washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to each of the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

**Facilities—** The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

**Selection of Subjects—** The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 24 subjects be used in this study. Subjects should be healthy, preferably nonsmoking, volunteers aged 18 to 55 and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of acceptable medical history, physical examination, and clinical laboratory test results. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. If smokers are included, they should be identified as such. Written, informed consent must be obtained from all study participants before they are accepted into the study.

**Procedure—** Following an overnight fast of at least 10 hours, subjects should be administered a single 600-mg dose (two 300-mg capsules or one 600-mg tablet) of the test or reference product with 240 mL of water.

**Restrictions—** Study volunteers should observe the following restrictions:

- a. Water may be taken except for 1 hour before and after drug administration when no liquid is allowed other than that needed for drug dosing.
- b. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- c. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- d. Subjects should take no Rx medications, including oral contraceptives, beginning 2 weeks and no OTC medications beginning 1 week before drug administration and until after the study is completed.

**Blood Sampling—** Venous blood samples should be collected pre-dose (0 hours) and at 0.5, 1, 1.5, 2, 2.5, 3, 4, 5, 6, 8, 10, 12, and 14 hours post-dose. Plasma should be separated promptly, stored in light resistant containers, and immediately frozen until assayed. Following a minimum 2-week washout period, subjects should begin the second phase of the study.

**Subject Monitoring—** Blood pressure and pulse rate should be monitored hourly during the first 4 hours of the study. Subjects with a heart rate less than 45 bpm or greater than 110 bpm should have an electrocardiogram (lead II) performed and have their pulse monitored hourly. Subjects should report any unusual symptoms observed during the study. Subjects should be periodically questioned during each phase of the study for any unusual symptoms experienced after drug administration.

**Analytical Methods—** Gemfibrozil should be assayed using a suitable method fully validated with respect to adequate sensitivity, specificity, linearity, recovery, accuracy, and precision (both within and between days). Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined.

**Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.**

**Statistical Analysis of Pharmacokinetic Data—** See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances.

**Clinical Report, Side Effects, and Adverse Reactions—** Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions and side effects to the study formulations should be reported.

**Retention of Samples—** The laboratory conducting the bioequivalence testing should retain appropriately identified reserve samples of both the test and reference products used to perform the in vivo bioequivalence studies for approval of the application. Each reserve sample should consist of at least 200 dosage units or 5 times the amount needed for complete release testing and should be retained for a minimum of 5 years following approval of the application. For more information on retention of bioequivalence samples refer to 21 CFR 320.63.

#### in vitro testing requirements

**Dissolution Testing—** Conduct dissolution testing on 12 dosage units of the test product and the reference product, employing the biostudy lots. The current official USP dissolution method in the monograph (see [Dissolution](#) 711) should be followed and should be referenced by the sponsor. The following times should be used to determine the dissolution profile:

Times: 15, 30, 45, and 60 minutes for capsules; and 10, 20, 30, and 45 minutes for tablets.

The percentage of label claim dissolved at each specified testing interval should be reported for each individual dosage unit. The mean percentage dissolved, the range of dissolution (highest, lowest), and the coefficient of variation (relative standard deviation) should be reported.

Content Uniformity Test—Content uniformity testing on the test and reference product lots should be performed as described in USP.

#### Glipizide Tablets—In Vivo Bioequivalence and In Vitro Dissolution Testing<sup>4</sup>

**Clinical Usage/Pharmacology**—Glipizide is an oral antidiabetic agent, which lowers blood glucose levels. It is approved for controlling blood glucose in noninsulin-dependent diabetes mellitus (NIDDM) patients whose blood glucose cannot be controlled by diet alone. Although the precise mechanism of hypoglycemic action of glipizide has not been clearly established, it appears to lower the blood glucose concentration mainly by stimulating endogenous insulin release from beta cells of the pancreas.

To achieve maximum reduction in the postprandial blood glucose concentration, glipizide should be administered 30 minutes before a meal. The recommended initial adult dose of glipizide is 5 mg daily, and the maximum recommended single daily dose is 15 mg. The optimum dosing regimen for each patient is obtained by titration. Glucose (urinary and blood) and blood glycosylated hemoglobin (Hb A1c) are used as the indicators of effective therapy. The most commonly observed adverse effects of glipizide are dizziness, sweating, tremors, and lightheadedness.

**Pharmacokinetics**—Glipizide is rapidly and completely absorbed after oral administration with a bioavailability of approximately 95%. After oral administration, the drug is 98.4% bound to plasma proteins, reaches Cmax in 1 to 3 hours, has an elimination half-life of 2 to 5 hours, and has a volume of distribution (Vd) of 11 L. Based on the mean plasma profiles, glipizide appears to exhibit either single compartment disposition or a very short distribution phase. The primary metabolites of glipizide are hydroxylation products and polar conjugates that are inactive and are excreted in both urine (70%) and feces. Biliary excretion is estimated to be approximately 30%. Less than 5% to 10% of the administered drug is excreted intact in urine. The extent of absorption of an oral dose of glipizide is unaffected by food in normal volunteers, but absorption is delayed by about 40 minutes. There are conflicting reports about the influence of food on Tmax. Plasma levels of glipizide in the range of 20 to 90 ng per mL have been reported as therapeutically effective.

#### in vivo bioequivalence studies<sup>5</sup>

##### Product Information—

FDA Designated Reference Product: Glucotrol® (Roerig) 10-mg tablets.

**Batch Size**—The test batch or lot must be manufactured under production conditions and must be of a size that is at least 10% of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.

**Potency**—The assayed potency of the reference product should not differ from that of the test product by more than 5%.

#### Types of Studies Required—

1. A single-dose, randomized, two-period, two-treatment, two-sequence crossover study under fasting conditions comparing equal doses of the test and reference products.
2. A single-dose, randomized, three-treatment, three-period, six-sequence, crossover, limited food effects study comparing equal doses of the test product under fasting conditions as well as the test and reference products when administered immediately following a standard high-fat breakfast.<sup>6</sup>

#### Recommended Protocol for Conducting a Single-Dose, Bioequivalence Study under Fasting Conditions—

**Objective**—The objective is to compare the rate and extent of absorption of a generic formulation with that of a reference formulation when given in equal labeled doses.

**Design**—The study design is a single-dose, two-treatment, two-period, two-sequence crossover with a 1-week washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to each of the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

**Facilities**—The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

**Selection of Subjects**—The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 24 subjects be used in this study. Subjects should be healthy, preferably nonsmoking, volunteers aged 18 to 50 years and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of an acceptable medical history, physical examination, and clinical laboratory test results. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. If smokers are included, they should be identified as such. Written, informed consent must be obtained from all study participants before they are accepted into the study.

**Procedure<sup>7</sup>**—Following an overnight fast of at least 10 hours, subjects should be administered a single dose (10 mg) of the test or reference product with 240 mL of a 20% glucose solution in water. After dosing, subjects should receive 60 mL of a 20% glucose solution in water every 15 minutes for 4 hours.

**Restrictions**—Study volunteers should observe the following restrictions:

- a. No additional water or fluids, except for the glucose solution, are allowed from 1 hour pre-dose to 1 hour post-dose.
- b. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- c. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- d. Subjects should take no Rx medication, including oral contraceptives, or OTC medication beginning 2 weeks before drug administration and until after the study is completed.

**Blood Sampling**—Venous blood samples should be collected pre-dose (0 hours) and at 0.50, 1, 1.50, 2, 3, 4, 5, 6, 8, 10, 12, 16, 24, and 36 hours post-dose. Plasma should be separated promptly and immediately frozen until assayed. Following a 1-week washout period, subjects should begin the second phase of the study. For each subject the sponsor should state the time elapsed between sample collection and its assay. An explanation should be given for any missing samples.

**Subject Monitoring**—Blood pressure and pulse rate should be monitored hourly during the first 4 hours of the study. Subjects with a heart rate less than 45 bpm or greater than 110 bpm should have an electrocardiogram (lead II) performed and have their pulse monitored hourly. Subjects should report any unusual symptoms observed during the study. Subjects should be periodically questioned during each phase of the study for any unusual symptoms experienced after drug administration.

**Analytical Methods**—The active ingredient should be assayed using a suitable method fully validated with respect to adequate sensitivity, specificity, linearity, recovery, accuracy, and precision (both within and between days). Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined. Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

**Statistical Analysis of Pharmacokinetic Data**—See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances.

**Limited Food Effects Study**—The limited food effects study should be performed in the same manner as the single-dose fasting study, with the following exceptions:

**Procedure**—An equal number of subjects should be assigned to each of the six dosing sequences possible in a three-treatment, three-period study design. Each subject will receive the following treatments:

TREATMENT 1: Generic product, a 10-mg glipizide tablet administered after a standard high-fat breakfast.

TREATMENT 2: Reference product, a 10-mg Glucotrol® tablet administered after a standard high-fat breakfast.

TREATMENT 3: Generic product, a 10-mg glipizide tablet administered under fasting conditions.

Following a 10-hour fast, the subjects receiving treatments under nonfasting conditions should be served a standard high-fat breakfast. The subjects should have 30 minutes to finish the entire breakfast, and then should immediately receive Treatment 1 or Treatment 2, with 240 mL of a 20% glucose solution in water. Subjects receiving the treatment under fasting conditions should be dosed with Treatment 3, taken with 240 mL of a 20% glucose solution in water. The same lots of the test and reference products should be used in the fasting and nonfasting studies. After dosing, each subject in all 3 treatments should receive 60 mL of a 20% glucose solution in water every 15 minutes for 4 hours. No food should be allowed for at least 4 hours post-dose, and no additional water or fluids should be allowed from 1 hour pre-dose to 1 hour post-dose. Subjects should be served scheduled, standardized meals

throughout the study, and the same meals should be served during both phases of the study.

**Statistical Analysis**— In general, a comparable food effect will be assumed if the AUC0-t, AUC0-, and Cmax mean values for the test product administered under nonfasting conditions are within 20% of the respective mean values for the reference product administered under nonfasting conditions.

**Clinical Report, Side Effects, and Adverse Reactions**— Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions to the study formulations should be reported.

**Retention of Samples**— The laboratory conducting the bioequivalence testing should retain appropriately identified reserve samples of both the test and reference products used to perform the in vivo bioequivalence studies for approval of the application. Each reserve sample should consist of at least 200 dosage units and should be retained for a minimum of 5 years after approval of the application. For more information on retention of bioequivalence samples, refer to 21 CFR 320.63.

#### in vitro testing requirements

**Dissolution Testing**— Conduct dissolution testing on 12 dosage units of the test and reference products, employing the biostudy lots. The current official USP dissolution method in the monograph should be followed and referenced by the sponsor. The following times should be used to determine the dissolution profile:

Times: 15, 30, 45, and 60 minutes.

**Content Uniformity Test** (905) — Content uniformity testing on the test and reference product lots should be performed as described in USP.

#### waiver requirements

Waiver of in vivo bioequivalence study requirements for the 5-mg strength of the generic product may be granted pursuant to 21 CFR 320.22(d)(2), provided the following conditions are met:

1. The 5-mg tablet is proportionally similar in both active and inactive ingredients to the 10-mg tablet, which has been demonstrated to be bioequivalent to the reference product in vivo.
2. The 5-mg tablet of the generic product meets the dissolution testing requirements.

#### Glyburide Tablets—In Vivo Bioequivalence and In Vitro Dissolution Testing<sup>4</sup>

**Clinical Usage/Pharmacology**— Glyburide is an oral antidiabetic agent, which lowers the blood glucose level. It is currently approved for controlling blood glucose in non-insulin-dependent diabetes mellitus (NIDDM) patients whose blood glucose cannot be controlled by diet alone. Glyburide acts mainly by stimulating endogenous insulin release from beta cells of the pancreas.

Glyburide is usually administered as a single daily dose each morning with breakfast or with the first main meal. The recommended initial adult dose is 2.5 to 5 mg daily for nonmicronized glyburide and 1.5 to 3 mg daily for micronized glyburide. The maximum recommended single daily dose is 10 mg for nonmicronized glyburide (up to 20 mg a day may be given in two divided doses) and 12 mg for micronized glyburide. The optimum dosing regimen of glyburide for each patient is obtained by titration. Glucose (urinary and blood) and blood glycosylated hemoglobin (Hb A1c) are used as the indicators of effective therapy. The most commonly observed adverse effects after administration of glyburide are dizziness or lightheadedness, which are due to hypoglycemia.

**Pharmacokinetics**— Glyburide is rapidly and completely absorbed after oral administration. As there is no significant first pass metabolism, 100% of the oral dose is bioavailable. After oral administration, nonmicronized glyburide reaches peak plasma or serum concentrations within 4 hours and exhibits an elimination half-life of 10 hours (more recently, half-lives of 1.4 to 5 hours have been reported). Micronized glyburide reaches peak concentrations within 2 to 3 hours and has a reported elimination half-life of about 4 hours. Glyburide concentration-time curves in plasma exhibit biphasic elimination. The primary metabolites of glyburide are hydroxylation products (4-trans-hydroxy and 3-cis-hydroxy derivatives) that are inactive and are excreted in urine (50%) and in feces (50%) via bile. Plasma levels of glyburide in the range of 20 to 90 ng per mL have been reported as therapeutically effective.

#### in vivo bioequivalence studies<sup>5</sup>

##### Product Information—

FDA Designated Reference Product: Micronase® (Pharmacia & Upjohn) 5-mg tablets, or Glynase® (Pharmacia & Upjohn) 6-mg tablets.

**Batch Size**— The test batch or lot must be manufactured under production conditions and must be of a size that is at least 10% of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.

**Potency**— The assayed potency of the reference product should not differ from that of the test product by more than 5%.

#### Types of Studies Required—

1. A single-dose, randomized, two-period, two-treatment, two-sequence crossover study under fasting conditions comparing equal 5-mg or 6-mg doses of the test and reference products.
2. A single-dose, randomized, three-treatment, three-period, six-sequence, crossover, limited food effects study comparing equal doses of the test product under fasting conditions as well as the test and reference products when administered immediately following a standard high-fat breakfast.<sup>6</sup>

#### Recommended Protocol for Conducting a Single-Dose Bioequivalence Study under Fasting Conditions—

**Objective**— The objective is to compare the rate and extent of absorption of a generic formulation with that of a reference formulation when given as equal labeled doses.

**Design**— The study design is a single-dose, two-treatment, two-period, two-sequence crossover with a 1-week washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to each of the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

**Facilities**— The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

**Selection of Subjects**— The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 24 subjects be used in this study. Subjects should be healthy, preferably nonsmoking, volunteers aged 18 to 50 years and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of an acceptable medical history, physical examination, and clinical laboratory test results. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. If smokers are included, they should be identified as such. Written, informed consent must be obtained from all study participants before they are accepted into the study.

**Procedure**— Following an overnight fast of at least 10 hours, subjects should be administered a single dose (5 mg or 6 mg) of the test or reference product with 240 mL of a 20% glucose solution in water. After dosing, the subjects should be given 60 mL of a 20% glucose solution in water, every 15 minutes for 4 hours.

**Restrictions**— Study volunteers should observe the following restrictions:

- a. No additional water or fluids, except the glucose solution, are allowed from 1 hour pre-dose to 1 hour post-dose.
- b. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- c. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- d. Subjects should take no Rx medications, including oral contraceptives, beginning 2 weeks, and no OTC medications beginning 1 week, before drug administration and until after the study is completed.

Blood Sampling— Venous blood samples should be collected predose (0 hours) and at 0.50, 1, 2, 3, 4, 5, 6, 8, 10, 12, 16, 24, 30, and 36 hours post-dose. Plasma should be separated promptly and immediately frozen until assayed. Following a 1-week washout period, subjects should begin the second phase of the study. For each subject, the sponsor should state the time elapsed between sample collection and its assay. An explanation should be given for any missing samples.

Subject Monitoring— Blood pressure and pulse rate should be monitored hourly during the first 4 hours of the study. Subjects with a heart rate less than 45 bpm or greater than 110 bpm should have an electrocardiogram (lead II) performed and have their pulse monitored hourly. Subjects should report any unusual symptoms observed during the study. Subjects should be periodically questioned during each phase of the study for any unusual symptoms experienced after drug administration.

Analytical Methods— The active ingredient should be assayed using a suitable method fully validated with respect to adequate sensitivity, specificity, linearity, recovery, and accuracy and precision (both within and between days). Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined. Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

Statistical Analysis of Pharmacokinetic Data— See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances.

Limited Food Effects Study— The limited food effects study should be performed in the same manner as the single-dose fasting study, with the following exceptions:

Procedure— An equal number of subjects should be assigned to each of the six dosing sequences possible in a three-treatment, three-period study design. Each subject will receive the following treatments:

TREATMENT 1: Generic product, a 5-mg glyburide tablet or a 6-mg micronized glyburide tablet, administered after a standard high-fat breakfast.

TREATMENT 2: Reference product, a 5-mg Micronase® tablet or a 6-mg Glynase® tablet, administered after a standard high-fat breakfast.

TREATMENT 3: Generic product, a 5-mg glyburide tablet or a 6-mg micronized glyburide tablet, administered under fasting conditions.

Following a 10-hour fast, the subjects receiving treatments under nonfasting conditions should be served a standard high-fat breakfast. The subjects should have 30 minutes to finish the entire breakfast, and then should immediately receive Treatment 1 or Treatment 2, with 240 mL of a 20% glucose solution in water. Subjects receiving the treatment under fasting conditions should receive Treatment 3, with 240 mL of a 20% glucose solution in water. The same lots of the test and reference products should be used in the fasting and nonfasting studies. After dosing, each subject in all 3 treatments should receive 60 mL of a 20% glucose solution in water every 15 minutes for 4 hours. No food should be allowed for at least 4 hours post-dose, and no additional water or fluids should be allowed from 1 hour pre-dose to 1 hour post-dose. Subjects should be served scheduled, standardized meals throughout the study, and the same meals should be served during both phases of the study.

Statistical Analysis— In general, a comparable food effect will be assumed if the AUC0-t, AUC0-∞, and Cmax mean values for the test product administered under nonfasting conditions are within 20% of the respective mean values for the reference product administered under nonfasting conditions.

Clinical Report, Side Effects, and Adverse Reactions— Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions to the study formulations should be reported.

Retention of Samples— The laboratory conducting the bioequivalence testing should retain appropriately identified reserve samples of both the test and reference products used to perform the in vivo bioequivalence studies for approval of the application. Each reserve sample should consist of at least 200 dosage units, and should be retained for a minimum of 5 years after approval of the application. For more information on retention of bioequivalence samples, refer to 21 CFR 320.63.

#### in vitro testing requirements

There is currently no official monograph for a glyburide dosage form in USP.

Content Uniformity Test (905)— Content uniformity testing on the test product lots should be performed as described in USP.

#### waiver requirements

Waiver of in vivo bioequivalence study requirements for the 1.25- and 2.5-mg strengths of the generic product may be granted pursuant to 21 CFR 320.22(d)(2), provided the following conditions are met:

1. The 1.25- and 2.5-mg tablets are proportionally similar in both active and inactive ingredients to the 5-mg tablet, which has been demonstrated to be bioequivalent to the reference product in vivo.
2. The 1.25- and 2.5-mg tablets of the generic product meet the dissolution testing requirements.

Waiver of in vivo bioequivalence requirements for the 1.5- and 3-mg strengths of the generic micronized product may be granted pursuant to 21 CFR 320.22(d)(2), provided the following conditions are met:

1. The 1.5- and 3-mg tablets are proportionally similar in both active and inactive ingredients to the 6-mg tablet, which has been demonstrated to be bioequivalent to the reference product in vivo.
2. The 1.5- and 3-mg tablets of the generic product meet the dissolution testing requirements.

#### Guanabenz Acetate—In Vivo Bioequivalence and In Vitro Dissolution Testing<sup>4</sup>

Clinical Pharmacology/Usage— Guanabenz acetate is a centrally acting antihypertensive agent. It appears to stimulate  $\alpha_2$ -adrenergic receptors in the CNS and cause inhibition of sympathetic outflow from the brain.

Guanabenz acetate is indicated in the treatment of hypertension and may be employed alone or in combination with a thiazide diuretic. It is contraindicated in patients with known hypersensitivity to the drug and should be used with caution in patients with hepatic or renal impairment, with cardiovascular diseases, during pregnancy, and in geriatric patients.

The side effects of guanabenz acetate are generally mild and may include a dry mouth, drowsiness or sedation, dizziness, weakness, and a headache. Abrupt withdrawal of guanabenz acetate (especially at doses  $\geq 32$  mg per day) may cause a rapid increase in serum catecholamine concentrations and systolic and diastolic blood pressures.

The initial dosage is 4 mg twice daily and may be gradually increased to a maximum of 32 mg twice daily.

Pharmacokinetics— Following an oral dose of guanabenz acetate, about 75% of the drug is absorbed. Because of extensive first-pass metabolism, the bioavailability is low—20% to 30% in monkeys—but the extent has not been established in man. A food effect on the drug absorption has not been determined.

Guanabenz acetate is rapidly and extensively distributed into the CNS and various organs. Following a 16-mg dose to fasting healthy individuals, peak plasma levels of unchanged drug are only 2.4 to 2.7 ng per mL at 2 to 5 hours with about 90% bound to proteins. For hepatically impaired patients, the Cmax is higher, 7.8 ng per mL. From the limited studies in humans, the concentration-time curves for the drug are best fit to a one- or two-compartment open model with a first-order absorption process and a lag time. The apparent steady-state volume of distribution is about 93 and 147 L per kg after 16- and 32-mg oral doses, respectively.

Therapeutic effects begin within 1 hour and last over 10 hours with a peak around 2 to 4 hours. At usual clinical doses, effects appear to be linearly related to dose.

The elimination half-life of guanabenz acetate averages 4 to 9 hours in healthy males. For liver impaired or hypertensive patients, the half-life averages 12 to 14 hours.

Guanabenz acetate metabolites—mainly from the liver—are excreted in urine (70% to 80% within 72 hours) and feces (10% to 30% in 6 days). One and four-tenths percent of the drug is excreted unchanged in the urine. Urinary metabolites include (E)-p-hydroxyguanabenz (11%), its glucuronide conjugate (25%), and the Z-guanabenz acetate (1.1%—the only active metabolite with about 25% parent drug activity).

in vivo bioequivalence studies<sup>5</sup>

## Product Information—

FDA Designated Reference Product: Wytenstir® (Wyeth-Ayerst) 8-mg tablet.

Batch Size— The test batch or lot must be manufactured under production conditions and must be of a size that is at least 10% that of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.

Potency— The assayed potency of the reference product should not differ from that of the test product by more than 5%.

Type of Study Required— A single-dose, randomized, two-period, two-treatment, two-sequence crossover study under fasting conditions comparing equal doses of the test and reference products.

## Recommended Protocol for Conducting a Single-Dose, Fasted Bioequivalence Study—

Objective— The objective is to compare the rate and extent of absorption of guanabenz acetate from a generic formulation with that of a reference formulation when given as equal labeled doses.

Design— The study design is a single-dose, two-treatment, two-period, two-sequence crossover with a 1-week washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to each of the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

Facilities— The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

Selection of Subjects— The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 24 subjects be used in this study. Subjects should be healthy, preferably nonsmoking, volunteers aged 18 to 50 and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of acceptable medical history, physical examination, and clinical laboratory test results. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. If smokers are included, they should be identified as such. Written, informed consent must be obtained from all study participants before they are accepted into the study.

Procedure— Following an overnight fast of at least 10 hours, subjects should be administered one 8-mg tablet of the test or reference product with 240 mL of water.

## Restrictions— Study volunteers should observe the following restrictions:

- a. Water may be taken except for 1 hour before and after drug administration when no liquid is allowed other than that needed for drug dosing.
- b. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- c. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- d. Subjects should take no Rx medications, including oral contraceptives, beginning 2 weeks and no OTC medications beginning 1 week before drug administration and until after the study is completed.

Blood Sampling— Venous blood samples should be collected pre-dose (0 hours) and at 0.50, 1, 1.50, 2, 2.50, 3, 3.50, 4, 6, 8, 12, 15, 24, 30, and 36 hours post-dose. Plasma should be separated promptly and immediately frozen until assayed. Following a minimum 1-week washout period, subjects should begin the second phase of the study.

Subject Monitoring— Blood pressure and pulse rate should be monitored hourly during the first 4 hours of the study. Subjects with a heart rate less than 45 bpm or greater than 110 bpm should have an electrocardiogram (lead II) performed and have their pulse monitored hourly. Subjects should report any unusual symptoms observed during the study. Subjects should be periodically questioned during each phase of the study for any unusual symptoms experienced after drug administration.

Analytical Methods— Guanabenz acetate should be assayed using a suitable method fully validated with respect to adequate sensitivity, specificity, linearity, recovery, accuracy, and precision (both within and between days). Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined. Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

Statistical Analysis of Pharmacokinetic Data— See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances.

Clinical Report, Side Effects, and Adverse Reactions— Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions and side effects to the study formulations should be reported.

Retention of Samples— The laboratory conducting the bioequivalence testing should retain appropriately identified reserve samples of both the test and reference products used to perform the in vivo bioequivalence studies for approval of the application. Each reserve sample should consist of at least 200 dosage units or 5 times the amount needed for complete release testing and should be retained for a minimum of 5 years following approval of the application. For more information on retention of bioequivalence samples, refer to 21 CFR 320.63.

## in vitro testing requirements

Dissolution Testing— Conduct dissolution testing on 12 dosage units of the test product and the reference product, employing the biostudy lots. [The current official USP dissolution method (see [Dissolution](#) 711) should be followed and should be referenced by the sponsor.] The following method and tolerances are currently recommended for this product: Medium: water; 1000 mL.

Apparatus 2: 50 rpm.

Times: 15, 30, 45, and 60 minutes.

Procedure— Use USP if available, or other validated method (see [Validation of Compendial Procedures](#) 1225).

Tolerance (Q): not less than 75% in 60 minutes.

The percentage of label claim dissolved at each specified testing interval should be reported for each individual dosage unit. The mean percentage dissolved, the range (highest, lowest) of dissolution, and the coefficient of variation (relative standard deviation) should be reported.

Content Uniformity Test— Content uniformity testing on the test and reference product lots should be performed as described in USP.

## waiver requirements

Waiver of in vivo bioequivalence study requirements for the 4-mg strength of the generic product may be granted pursuant to 21 CFR 320.22(d)(2), provided the following conditions are met:

1. The 4-mg tablet is proportionally similar in both active and inactive ingredients to the firm's 8-mg tablet, which has been demonstrated to be bioequivalent to the reference product in vivo.
2. The 4-mg tablet of the generic product meets dissolution test requirements.

Hydroxychloroquine Sulfate Tablets—In Vivo Bioequivalence and In Vitro Dissolution Testing<sup>4</sup>

Clinical Usage/Pharmacology— Hydroxychloroquine sulfate is indicated for the suppressive treatment and treatment of acute attacks of malaria due to *Plasmodium vivax*, *P. malariae*, *P. ovale*, and susceptible strains of *P. falciparum*. It is also indicated for the treatment of discoid and systemic lupus erythematosus and rheumatoid arthritis. Use of this drug is

contraindicated in the presence of retinal or visual field changes attributable to any 4-aminoquinoline compound.

The exact mechanism of antimalarial activity of hydroxychloroquine and the mechanism of action of the drug in the treatment of rheumatoid arthritis and lupus erythematosus have not been determined. However, the actions of the drug are presumably the same as those of chloroquine. Dosage and administration are dependent on the indications.

**Pharmacokinetics**— Information in literature on the pharmacokinetics of hydroxychloroquine is scarce. The mean bioavailability of hydroxychloroquine after oral administration is 74%. A 200-mg dose given orally resulted in a Cmax in whole blood of 120 to 170 ng per mL and a Tmax of 3 to 4 hours. Terminal half-life ranged from 19 to 28 days. After intravenous administration, hydroxychloroquine was found to have a large volume of distribution (5,500 L from blood, 44,000 L from plasma) and a terminal elimination half-life of approximately 40 days. It may require 6 months to achieve a steady-state blood level at a 200 mg per day dosing regimen.

#### in vivo bioequivalence studies<sup>5</sup>

##### Product Information—

FDA Designated Reference Product: Plaquenil® (Sanofi Winthrop) 200-mg tablet.

**Batch Size**— The test batch or lot must be manufactured under production conditions and must be of a size that is at least 10% of the largest lot planned for full production or a minimum of 100,000 dosage units, whichever is larger.

**Potency**— The assayed potency of the reference product should not differ from that of the test product by more than 5%.

##### Types of Studies Required—

1. A single-dose, randomized, two-period, two-treatment, two-sequence, crossover study under fasting conditions comparing equal doses of the test and reference products.
2. A single-period, parallel study comparing equal doses of the test and reference products.

##### Recommended Protocol for Conducting a Single-Dose Bioequivalence Study under Fasting Conditions—

**Objective**— The objective is to compare the rate and extent of absorption of a generic formulation with that of the reference formulation when given as equal labeled doses.

**Design**— The study design is a single-dose, two-treatment, two-period, two-sequence, crossover study with a washout period of at least 4 months. An equal number of subjects should be randomly assigned to the two possible dosing sequences. As an alternative, the design may be a single-dose, randomized, two-treatment, one-period, parallel study with a blood sampling time of approximately 3 months. Before the study begins, the proposed protocol should be approved by an institutional review board.

**Facilities**— The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of medical and scientific or analytical directors.

**Selection of Subjects**— The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 48 subjects be used for crossover studies or 96 subjects for parallel studies. Subjects should be healthy, preferably nonsmoking, volunteers aged 18 to 50 years and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of acceptable medical history, physical examination, and clinical laboratory test results. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. If smokers are included, they should be identified as such. Written, informed consent must be obtained from all study participants before they are accepted into the study.

**Procedure**— Following an overnight fast of at least 10 hours, subjects should be administered a single dose of the test or reference product with 240 mL of water.

##### Restrictions— Study volunteers should observe the following restrictions:

- a. The subjects should fast for 5 hours post-dose. Water may be taken except for 2 hours after drug administration.
- b. No xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until 24 hours post-dose.
- c. No alcoholic beverages should be consumed for 48 hours prior to and during the study period.
- d. Subjects should take no Rx medications, including oral contraceptives, beginning 2 weeks and no OTC medications beginning 1 week before drug administration and until after the study is completed.

**Blood Sampling**— Venous blood samples should be collected into tubes containing an anti-coagulant pre-dose (0 hours), and at 0.5, 1, 1.5, 2, 2.5, 3, 4, 5, 6, 8, 10, 12, 24, 36, 48, 72, 96, 120 hours and at 8, 12, 15, 19, 22, 26, 29, 33, 36, 43, 50, 57, 64, 70, 80, and 90 days. Blood should be immediately frozen until assayed.

**Subject Monitoring**— Blood pressure and pulse rate should be monitored hourly during the first 4 hours of the study. Subjects with a heart rate less than 45 bpm or greater than 110 bpm should have an electrocardiogram (lead II) performed and have their pulse monitored hourly. Subjects should report any unusual symptoms observed during the study. Subjects should be periodically questioned during each phase of the study for any unusual symptoms experienced after drug administration. A physical examination and clinical laboratory tests should be repeated after completing the blood level study.

**Analytical Methods**— Hydroxychloroquine in whole blood should be assayed using a suitable method fully validated with respect to adequate sensitivity, specificity, linearity, recovery, accuracy, and precision (both within and between days). The method to be used should be specific enough to measure the parent drug without interferences from metabolites and endogenous or exogenous components in the blood. Stability of samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined. Chromatograms of the analysis of the unknown samples, including all associated standard curves and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

**Pharmacokinetic Analysis**— From the blood drug concentration-time data, the following pharmacokinetic parameters should be determined for hydroxychloroquine:

- a. Area under the concentration-time curve from time zero to time t (AUC<sub>0-t</sub>), calculated by the trapezoidal rule, where t is the last time point with measurable non-zero concentration.
- b. Area under the concentration-time curve from time zero to time infinity (AUC<sub>0-∞</sub>), where AUC<sub>0-∞</sub> = AUC<sub>0-t</sub> + Ct / λ<sub>z</sub>, Ct is the last measurable non-zero concentration, and λ<sub>z</sub> is the terminal elimination rate constant calculated using an appropriate method.
- c. The terminal phase elimination rate constant, λ<sub>z</sub>, and the elimination half-life are calculated using an appropriate method.
- d. Peak drug concentration, C<sub>max</sub>, and the time to peak drug concentration, T<sub>max</sub>, are obtained directly from the data without interpolation.

**Statistical Analysis of Pharmacokinetic Data**— See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment, Crossover Design under General Guidances; and an appropriate model should be chosen for the parallel study.

**Clinical Report, Side Effects, and Adverse Reactions**— Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions to the study formulations should be reported.

**Retention of Samples**— The laboratory conducting the bioequivalence testing should retain an appropriately identified reserve sample of both the test and reference products used to perform the in vivo bioequivalence study for approval of the application. Each reserve sample should consist of at least 200 dosage units or 5 times the amount needed for complete release testing and should be retained for a minimum of 5 years following approval of the application. For more information on retention of bioequivalence samples, refer to 21 CFR 320.63.

##### in vitro testing requirements

**Dissolution Testing**— Conduct dissolution testing on 12 dosage units of the test and reference products, employing the biostudy lots. The current official USP dissolution method should be followed and should be referenced by the sponsor. The following times should be used to determine the dissolution profile:

Times: 15, 30, 45, and 60 minutes.

The percentage of label claim dissolved at each specified sampling interval should be reported for each individual dosage unit. The mean percentage dissolved, the range of dissolution (highest and lowest), and the coefficient of variation (relative standard deviation) should be reported.

Content Uniformity Tests [905](#) — Content uniformity testing on the test and reference product lots should be performed as described in USP.

#### Indapamide Tablets— In Vivo Bioequivalence and In Vitro Dissolution Testing<sup>4</sup>

**Clinical Pharmacology/Usage—** Indapamide is indicated for the treatment of hypertension, alone or in combination with other antihypertensive drugs. It is also indicated for the treatment of salt and fluid retention associated with congestive heart failure. The recommended daily dose of indapamide is 2.5 mg, to be taken in the morning, which may be increased to 5.0 mg taken once daily.

Like other thiazide diuretics, indapamide works in the cortical diluting segment of the distal renal tubule. It acts on the luminal surface of the tubule, probably by inhibiting the Na<sup>+</sup>-Cl<sup>-</sup> co-transporter. Diuretic effects of indapamide are linearly related to dose in the range of 0.5 to 20 mg per day. The mechanism of antihypertensive action of indapamide is not established, and the magnitude of change in blood pressure does not correlate directly with change in extracellular fluid or plasma volume. A variety of actions of indapamide have been reported that may contribute to its antihypertensive activity. These effects include a decrease in the inward calcium current in the vascular smooth muscle, antipressor activity, and release of vasodilator prostaglandins such as prostaglandin E2 and prostacyclin. The net effect of indapamide may depend upon which of the various effects is dominant and may exhibit inter-patient variation.

**Pharmacokinetics—** The absorption of indapamide in healthy volunteers following oral administration is rapid and complete. The bioavailability of indapamide from oral solution and tablets is similar and is unaffected when the drug is given with food or antacids. The peak blood concentration, which exhibits linearity following administration of indapamide in doses of 2.5- to 10-mg, occurs 0.5 to 2 hours after drug administration. Steady-state blood concentration of indapamide is attained after 4 daily doses of 2.5 or 5.0 mg. Indapamide is readily taken up by erythrocytes. In human volunteers, a blood to plasma indapamide ratio of 5.7:1 at peak concentration has been reported, and its volumes of distribution estimated from blood and plasma concentrations are approximately 25 L per kg (V1) and 110 L per kg (V2), respectively. Indapamide is approximately 76% to 79% protein bound. Blood concentrations of indapamide exhibit biexponential decay with a rapid  $\alpha$ -phase and a prolonged  $\beta$ -phase. The terminal-phase elimination half-life of indapamide is in the range of 13 to 18 hours.

In humans, the major route of indapamide elimination is the urine, where 60% to 70% of an orally administered dose may be excreted. The estimated total systemic clearance of indapamide is in the range of 20 to 23.4 mL per minute. Because renal clearance of indapamide is only 1.71 mL per minute, hepatic clearance (23.8 mL per minute) may be responsible for a major portion of systemic clearance. Fecal elimination accounts for 16% to 23% of an orally administered dose. Indapamide is extensively metabolized in the liver. Up to 7% of the administered dose is excreted unchanged; the remainder as metabolites. In human volunteers, anywhere from 5 to 19 metabolic products of indapamide have been reported.

#### in vivo bioequivalence studies<sup>5</sup>

##### Product Information—

FDA Designated Reference Product: Lozol® (Rhône-Poulenc Rorer) 2.5-mg tablets.

**Batch Size—** The test batch or lot must be manufactured under production conditions and must be of a size that is at least 10% that of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.

**Potency—** The assayed potency of the reference product should not differ from that of the test product by more than 5%.

**Type of Study Required—** A single-dose, randomized, two-period, two-treatment, two-sequence crossover study under fasting conditions comparing equal doses of the test and reference products.

#### Recommended Protocol for Conducting a Single-Dose Bioequivalence Study under Fasting Conditions—

**Objective—** The objective is to compare the rate and extent of absorption of a generic formulation with that of a reference formulation when given as equal labeled doses.

**Design—** The study design is a single-dose, two-treatment, two-period, two-sequence crossover with a 2-week washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to each of the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

**Facilities—** The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

**Selection of Subjects—** The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 24 subjects be used in this study. Subjects should be healthy, preferably nonsmoking, volunteers aged 18 to 50 and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of an acceptable medical history, physical examination, and clinical laboratory test results. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. If smokers are included, they should be identified as such. Written, informed consent must be obtained from all study participants before they are accepted into the study.

**Procedure—** Following an overnight fast of at least 10 hours, subjects should be administered two 2.5-mg tablets of the test or reference product with 240 mL of water.

**Restrictions—** Study volunteers should observe the following restrictions:

- a. Water may be taken, except for 1 hour before and after drug administration when no liquid is allowed other than that needed for drug dosing.
- b. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- c. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- d. Subjects should take no Rx medications, including oral contraceptives, beginning 2 weeks and no OTC medications beginning 1 week before drug administration and until after the study is completed.

**Blood Sampling—** Because indapamide binds preferentially to erythrocytes, its concentration as determined using plasma may not reflect true amounts of drug in the body if the hematocrit is altered within or between treatments. Therefore, whole blood concentrations of indapamide should be assayed. Venous blood samples should be collected pre-dose (0 hours) and at 0.50, 1, 1.50, 2, 2.50, 3, 4, 6, 8, 10, 12, 16, 24, 36, 48, 72 and 96 hours post-dose. Blood should be immediately frozen until assayed. Following a minimum 2-week washout period, subjects should begin the second phase of the study.

**Subject Monitoring—** Blood pressure and pulse rate should be monitored hourly during the first 4 hours of the study. Subjects with a heart rate less than 45 bpm or greater than 110 bpm should have an electrocardiogram (lead II) performed and have their pulse monitored hourly. Subjects should report any unusual symptoms observed during the study. Subjects should be periodically questioned during each phase of the study for any unusual symptoms experienced after drug administration.

**Analytical Methods—** Indapamide should be assayed using a suitable method fully validated with respect to adequate sensitivity, specificity, linearity, recovery, accuracy, and precision (both within and between days). Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined. Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

**Statistical Analysis of Pharmacokinetic Data—** See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances.

**Clinical Report, Side Effects, and Adverse Reactions—** Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions and side effects to the study formulations should be reported.

**Retention of Samples—** The laboratory conducting the bioequivalence testing should retain appropriately identified reserve samples of both the test and reference products used to perform the in vivo bioequivalence studies for approval of the application. Each reserve sample should consist of at least 200 dosage units or 5 times the amount needed for complete release testing and should be retained for a minimum of 5 years following approval of the application. For more information on retention of bioequivalence samples, refer to 21 CFR

320.63.

## in vitro testing requirements

Dissolution Testing—Conduct dissolution testing on 12 dosage units of the test product versus 12 units of the reference product. The biostudy lots should be used for those product strengths tested in vivo. The current official USP dissolution method should be followed and should be referenced by the sponsor.

Times: 15, 30, 45, and 60 minutes.

Content Uniformity Test (905)—Content uniformity testing on the test and reference product lots should be performed as described in USP.

## waiver requirements

Waiver of in vivo bioequivalence study requirements for the 1.25-mg strength of the generic product may be granted pursuant to 21 CFR 320.22(d)(2), provided the following conditions are met:

1. The 1.25-mg tablet is proportionally similar in both active and inactive ingredients to the firm's 2.5-mg tablet, which has been demonstrated to be bioequivalent to the reference product in vivo.
2. The 1.25-mg tablet of the generic product meets dissolution test requirements.

Ketoprofen Capsules—In Vivo Bioequivalence and In Vitro Dissolution Testing<sup>4</sup>

Clinical Usage/Pharmacology—Ketoprofen is a nonsteroidal anti-inflammatory drug with analgesic and antipyretic properties. It is indicated for the acute or long-term treatment of the signs and symptoms of rheumatoid arthritis and osteoarthritis. Ketoprofen is contraindicated in patients who are hypersensitive to aspirin and other nonsteroidal anti-inflammatory drugs. Monitoring of renal function is indicated in patients taking concomitant diuretics.

Ketoprofen curtails the inflammatory mechanism in rheumatoid arthritis and other disease states by reversibly inhibiting cyclooxygenase and lipoxygenase, enzymes involved in the synthesis of prostaglandins and leukotrienes. It is also a powerful inhibitor of bradykinin, a pain and inflammation mediator, and prevents the release of lysosomal enzymes, which can cause tissue destruction in inflammatory reactions.

For rheumatoid arthritis and osteoarthritis in adults, an initial dose of 75 mg 3 times or 50 mg 4 times a day is recommended. In patients who tolerate ketoprofen well, a maximum total daily dose of 300 mg can be used. Ketoprofen should be taken with food or milk.

Pharmacokinetics—Ketoprofen is rapidly and completely absorbed from the gastrointestinal tract with peak plasma concentration occurring in 0.5 to 2 hours. The mean plasma elimination half-life ranges from 2 to 4 hours. The absolute bioavailability of the 100-mg capsule of ketoprofen as compared to an intravenous formulation is  $\geq 92\%$ . Concurrent ingestion of food appears to affect the rate but not the extent of absorption of ketoprofen.

Ketoprofen is more than 95% bound to plasma albumin with a relatively small apparent volume of distribution ( $V_d = 0.1-0.2 \text{ L per kg}$ ). Substantial concentrations of ketoprofen have been found in synovial fluid, which is the proposed primary site of action for NSAIDS in rheumatoid arthritis. Ketoprofen exhibits a longer  $T_{max}$ , a lower  $C_{max}$ , and a 2.5-fold greater elimination half-life in synovial fluid than in plasma.

Two studies in humans have shown that 90% of an oral dose of tritiated ketoprofen given to healthy subjects was recovered in the urine over several days; an additional 1% to 8% of the labeled dose appeared in the feces. Virtually all of the material eliminated into urine after an oral dose is in the form of ketoprofen conjugates; less than 1% is the unchanged drug.

Enterohepatic recirculation appeared to be negligible in humans. Ketoprofen metabolites are not active.

in vivo bioequivalence studies<sup>5</sup>

## Product Information—

FDA Designated Reference Product: Orudis® (Wyeth Ayerst) 75-mg capsules.

Batch Size—The test batch or lot must be manufactured under production conditions and must be of a size that is at least 10% of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.

Potency—The assayed potency of the reference product should not differ from that of the test product by more than 5%.

## Types of Studies Required—

1. A single-dose, randomized, two-period, two-treatment, two-sequence crossover study under fasting conditions comparing equal doses of the test and reference products.
2. A single-dose, randomized, three-treatment, three-period, six-sequence crossover, limited food effects study comparing equal doses of the test and reference products when administered immediately following a standard high-fat breakfast.<sup>6</sup>

## Recommended Protocol for Conducting a Single-Dose Bioequivalence Study under Fasting Conditions—

Objective—The objective is to compare the rate and extent of absorption of a generic formulation with that of a reference formulation when given as equal labeled doses.

Design—The study design is a single-dose, two-treatment, two-period, two-sequence crossover with a 1-week washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to each of the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

Facilities—The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

Selection of Subjects—The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 24 subjects be used in this study. Subjects should be healthy, preferably nonsmoking, volunteers 18 to 50 years of age and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of an acceptable medical history, physical examination, and clinical laboratory test results. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. If smokers are included, they should be identified as such. Written, informed consent must be obtained from all study participants before they are accepted into the studies.

Procedure—Following an overnight fast of at least 10 hours, subjects should be administered a single 75-mg tablet of the test or reference product with 240 mL of water.

Restrictions—Study volunteers should observe the following restrictions:

- a. Water may be taken, except for 1 hour before and after drug administration, when no liquid is allowed other than that needed for drug dosing.
- b. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- c. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- d. Subjects should take no Rx medications, including oral contraceptives, beginning 2 weeks and no OTC medications beginning 1 week before drug administration and until after the study is completed.

Blood Sampling—Venous blood samples should be collected pre-dose (0 hours) and at 10, 20, 30, and 45 minutes and at 1, 1.25, 1.50, 2, 2.50, 3, 4, 6, 8, 10, 12, 16, and 24 hours post-dose. Plasma should be separated promptly and immediately frozen until assayed. Following a minimum 1-week washout period, subjects should begin the second phase of the study.

Analytical Methods—The active ingredient should be assayed using a suitable method fully validated with respect to adequate sensitivity, specificity, linearity, recovery, and accuracy and precision (both within and between days). Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be

determined. Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

**Subject Monitoring**—Blood pressure and pulse rate should be monitored hourly during the first 4 hours of the study. Subjects with a heart rate less than 45 bpm or greater than 110 bpm should have an electrocardiogram (lead II) performed and have their pulse monitored hourly. Subjects should report any unusual symptoms observed during the study. Subjects should be periodically questioned during each phase of the study for any unusual symptoms experienced after drug administration.

**Statistical Analysis of Pharmacokinetic Data**—See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances.

#### Limited Food Effects Study—

**Objective**—The objective is to compare the rate and extent of absorption of ketoprofen from a generic formulation with that from a reference formulation under nonfasting conditions and to compare the rate and extent of absorption of the drug from a generic formulation under fasting and nonfasting conditions when given as equal labeled doses.

**Design**—The study design is a single-dose, three-treatment, three-period, six-sequence crossover with a 1-week washout period between Phase I and Phase II, and Phase II and Phase III. An equal number of subjects should be assigned to each of the six dosing sequences.

The limited food effects study should be performed in the same manner as the single-dose study under fasting conditions, with the following exceptions:

**Procedure**—An equal number of subjects (12 to 18) should be assigned to each of the six dosing sequences possible in a three-treatment, three-period study design. Each subject will receive the following treatments:

TREATMENT 1: Generic product, a 75-mg capsule administered after a standard high-fat breakfast.

TREATMENT 2: Reference product, a 75-mg Orudis® capsule administered after a standard high-fat breakfast.

TREATMENT 3: Generic product, a 75-mg capsule administered under fasting conditions.

Following a 10-hour fast, the subjects receiving treatments under fed conditions should be served a standard high-fat breakfast. The subjects should have 30 minutes to finish the entire breakfast, and then should immediately receive Treatment 1 or Treatment 2, taken with 240 mL of water. Subjects receiving the treatment under fasting conditions should receive Treatment 3, taken with 240 mL of water only. The same lots of the test and reference products should be used in the fasting and nonfasting studies. No food should be allowed for at least 4 hours post-dose with water allowed after the first hour. Subjects should be served scheduled standardized meals throughout the study, and the same meals should be served during all phases of the study.

**Statistical Analysis**—In general, a comparable food effect will be assumed if the AUC0–t, AUC0–, and Cmax mean values for the test product administered under nonfasting conditions are within 20% of the respective mean values obtained for the reference product administered under nonfasting conditions.

**Clinical Report, Side Effects, and Adverse Reactions**—Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions and side effects to the study formulations should be reported.

**Retention of Samples**—The laboratory conducting the bioequivalence testing should retain appropriately identified reserve samples of both the test and reference products used to perform the in vivo bioequivalence studies for approval of the application. Each reserve sample should consist of at least 200 dosage units and should be retained for a minimum of 5 years following approval of the application. For more information on retention of bioequivalence samples, refer to 21 CFR 320.63.

#### in vitro testing requirements

**Dissolution Testing** (711)—Conduct dissolution testing on 12 dosage units of the test product and reference products, employing the biostudy lots. The following method and tolerances are currently recommended for this product:

Medium: 0.05 M pH 7.4 phosphate buffer; 1000 mL.

Apparatus 2: 50 rpm.

Times: 10, 20, and 30 minutes.

**Procedure**—Use USP if available, or other validated method (see [Validation of Compendial Procedures](#) (1225)).

Tolerances (Q): not less than 80% in 30 minutes.

The percentage of label claim dissolved at each specified testing interval should be reported for each individual dosage unit. The mean percentage dissolved, the range (highest, lowest) of dissolution, and the coefficient of variation (relative standard deviation) should be reported.

**Content Uniformity Test** (905)—Content uniformity testing on the test and reference product lots should be performed as described in USP.

#### waiver requirements

Waiver of in vivo bioequivalence study requirements for the 25- and 50-mg strengths of the generic capsule may be granted pursuant to 21 CFR 320.22(d)(2), provided the following conditions are met:

1. The 25- and 50-mg capsules are proportionally similar in both active and inactive ingredients to the firm's 75-mg capsule, which has been demonstrated to be bioequivalent to the reference product in vivo.
2. The 25- and 50-mg capsules meet the dissolution test requirements.

#### Nadolol Tablets—In Vivo Bioequivalence and In Vitro Dissolution Testing<sup>4</sup>

**Clinical Pharmacology/Usage**—Nadolol is a long-acting, synthetic, nonselective beta-adrenergic receptor blocker. Currently approved indications include treatment of essential hypertension and treatment of angina pectoris.

For the treatment of hypertension, the usual initial dose is 40 mg of nadolol once daily. The dosage may be gradually increased in 40- to 80-mg increments until optimum blood pressure reduction is achieved. The usual maintenance dose is 40 or 80 mg once daily. Doses of up to 240 or 320 mg administered once daily may be needed.

For the treatment of angina pectoris, the usual initial dose is 40 mg of nadolol once daily. The dosage may be gradually increased in 40- to 80-mg increments at three- to five-day intervals until optimum clinical response is obtained or there is pronounced slowing of the heart rate. The usual maintenance dose is 40 or 80 mg once daily. Doses of up to 160 or 240 mg administered once daily may be needed.

Nadolol specifically competes with beta-adrenergic receptor agonists for available beta receptor sites; it inhibits both the beta-1 receptors located chiefly in the cardiac muscle and the beta-2 receptors located chiefly in the bronchial and vascular musculature, proportionately inhibiting the chronotropic, inotropic, and vasodilator responses to beta-adrenergic stimulation. Nadolol is contraindicated in cases of bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure.

**Pharmacokinetics**—The absorption of nadolol from the GI tract is variable following oral dosing, averaging about 30%. About 20% to 30% of the drug is reversibly bound to plasma proteins. Peak blood serum concentrations are reached within 1 to 4 hours following oral administration. The elimination half-life is in the range of 12 to 24 hours, permitting once-daily administration. Steady-state serum levels are reached in 6 to 9 days with once-daily dosing. Because nadolol is excreted unchanged predominately in the urine, its half-life increases in patients with renal impairment.

Pharmacokinetically, the drug is described by an open, two-compartment model. The approved labeling for the drug states that the presence of food in the GI tract does not affect the rate or extent of absorption and that nadolol may be dosed without regard to meals.

#### in vivo bioequivalence studies<sup>5</sup>

## Product Information—

FDA Designated Reference Products: Corgard® (Bristol Laboratories) 40- and 160-mg tablets.

**Batch Size**— The test batch or lot must be manufactured under production conditions and must be of a size at least 10% that of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.

**Potency**— The assayed potency of the reference product should not differ from that of the test product by more than 5%.

## Types of Studies Required—

1. Two single-dose, randomized, two-period, two-treatment, two-sequence crossover studies under fasting conditions comparing equal doses of the 40- and 160-mg test and reference products.
2. A single-dose, randomized, three-treatment, three-period, six-sequence crossover, limited food effects study comparing equal doses of the 40-mg test and reference products when administered immediately following a standard high-fat breakfast.<sup>§</sup>

## Recommended Protocols for Conducting Single-Dose, Fasted Bioequivalence Studies—

**Objective**— The objective of the two studies is to compare the rate and extent of absorption of nadolol from generic formulations with that from reference formulations when given as equal labeled doses.

**Design**— The study design is a single-dose, two-treatment, two-period, two-sequence crossover with a 2-week washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to each of the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

**Facilities**— The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

**Selection of Subjects**— The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. Subjects should be healthy, preferably nonsmoking, volunteers aged 18 to 55 and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of acceptable medical history, physical examination, and clinical laboratory test results. Subjects should have a resting pulse rate of at least 65 bpm. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. If smokers are included, they should be identified as such. Written, informed consent must be obtained from all study participants before they are accepted into the study.

**Procedure**— Following an overnight fast of at least 10 hours, subjects should be administered a single dose (40 or 160 mg) of the test or reference product with 240 mL of water.

## Restrictions— Study volunteers should observe the following restrictions:

- a. Water may be taken, except for 1 hour before and after drug administration, when no liquid is allowed other than that needed for drug dosing.
- b. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- c. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- d. Subjects should take no Rx medications, including oral contraceptives, beginning 2 weeks and no OTC medications beginning 1 week before drug administration and until after the study is completed.

**Blood Sampling**— Venous blood samples should be collected pre-dose (0 hours) and at 0.50, 1, 1.5, 2, 3, 4, 5, 6, 8, 12, 18, 24, 36, 48, and 72 hours post-dose. Plasma should be separated promptly and immediately frozen until assayed. Following a minimum 2-week washout period, subjects should begin the second phase of the study.

**Subject Monitoring**— Blood pressure and pulse rate should be monitored hourly during the first 4 hours of the study. Subjects with a heart rate less than 45 bpm or greater than 110 bpm should have an electrocardiogram (lead II) performed and have their pulse monitored hourly. Subjects should report any unusual symptoms observed during the study. Subjects should be periodically questioned during each phase of the study for any unusual symptoms experienced after drug administration.

**Analytical Methods**— Nadolol should be assayed using a suitable method fully validated with respect to adequate sensitivity, specificity, linearity, recovery, accuracy, and precision (both within and between days). Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined.

Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

**Statistical Analysis of Pharmacokinetic Data**— See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances.

## Limited Food Effects Study—

**Objective**— The objective is to compare the rate and extent of absorption of nadolol from a generic formulation with that from a reference formulation under nonfasting conditions and to compare the rate and extent of absorption of the drug from a generic formulation under fasting and nonfasting conditions when given as equal labeled doses.

**Design**— The study design is a single-dose, three-treatment, three-period, six-sequence crossover with a 2-week washout period between Phase I and Phase II and Phase II and Phase III.

The limited food effects study (minimum 12 subjects) should be performed in the same manner as the single-dose study under fasting conditions, with the following exceptions:

**Procedure**— An equal number of subjects should be assigned to each of the 6 dosing sequences possible in a three-treatment, three-period study design. Each subject will receive the following treatments:

TREATMENT 1: Generic product, a 40-mg tablet administered after a standard high-fat breakfast.

TREATMENT 2: Reference product, a 40-mg Corgard® tablet administered after a standard high-fat breakfast.

TREATMENT 3: Generic product, a 40-mg tablet administered under fasting conditions.

Following a 10-hour fast, the subjects receiving treatments under fed conditions should be served a standard high-fat breakfast. The subjects should have 30 minutes to finish the entire breakfast and then should immediately receive Treatment 1 or Treatment 2, taken with 240 mL of water. Subjects receiving the treatment under fasting conditions should receive Treatment 3, taken with 240 mL of water only. The same lots of the test and reference products should be used in the fasted and fed studies. No food should be allowed for at least 4 hours post-dose, with water allowed after the first hour. Subjects should be served scheduled standardized meals throughout the study, and the same meals should be served during all phases of the study.

**Statistical Analysis**— In general, a comparable food effect will be assumed if the AUC<sub>0-t</sub>, AUC<sub>0-∞</sub>, and C<sub>max</sub> mean values for the test product administered under fed conditions are within 20% of the respective mean values obtained for the reference product administered under fed conditions.

**Clinical Report, Side Effects, and Adverse Reactions**— Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions and side effects to the study formulations should be reported.

**Retention of Samples**— The laboratory conducting the bioequivalence testing should retain appropriately identified reserve samples of both the test and reference products used to perform the in vivo bioequivalence studies for approval of the application. Each reserve sample should consist of at least 200 dosage units or 5 times the amount needed for complete release testing, whichever is greater, and should be retained for a minimum of 5 years following approval of the application. For more information on retention of bioequivalence samples, refer to 21 CFR 320.63.

## in vitro testing requirements

**Dissolution Testing**— Conduct dissolution testing on 12 dosage units of the test and reference products, employing the biostudy lots. The current official USP dissolution method (see

[Dissolution](#) (711) should be followed and referenced by the sponsor. The following times should be used to determine the dissolution profile:  
Times: 10, 20, 30, 40, 50, and 60 minutes.

The percentage of label claim dissolved at each specified testing interval should be reported for each individual dosage unit. The mean percentage dissolved, the range of dissolution (highest, lowest), and the coefficient of variation (relative standard deviation) should be reported.

Content Uniformity Test—Content uniformity testing on the test and reference product lots should be performed as described in USP.

#### waiver requirements

Waiver of in vivo bioequivalence study requirements for the 20-, 80- and 120-mg strengths of the generic product may be granted pursuant to 21 CFR 320.22(d)(2) provided the following conditions are met:

1. The 20-mg tablet is proportionally similar in both active and inactive ingredients to the firm's 40-mg tablet, which has been demonstrated to be bioequivalent to the reference product in vivo. The 80- and 120-mg tablets are proportionally similar in both active and inactive ingredients to the firm's 160-mg tablet, which has been demonstrated to be bioequivalent to the reference product in vivo.
2. The 20-mg tablet of the generic product meets dissolution test requirements. The 80- and 120-mg tablets of the generic product meet dissolution test requirements.

#### Naproxen Tablets—In Vivo Bioequivalence and In Vitro Dissolution Testing<sup>4</sup>

**Clinical Pharmacology/Usage**— Naproxen is an orally administered nonsteroidal anti-inflammatory drug (NSAID), which also has analgesic and antipyretic properties. Currently approved indications for naproxen are (1) treatment of rheumatoid arthritis, osteoarthritis, juvenile arthritis, ankylosing spondylitis, tendinitis, bursitis, and acute gout; (2) relief of mild to moderate pain; and (3) treatment of primary dysmenorrhea. For adult arthritis and ankylosing spondylitis, the recommended dosage is 250-500 mg bid (morning and evening), up to 1500 mg per day for limited periods when a higher degree of anti-inflammatory activity is required and the dose is well tolerated. For juvenile arthritis, the recommended total daily dose of naproxen is 10 mg per kg in two divided doses. For acute gout, the recommended starting dose is 750 mg followed by 250 mg every 8 hours until the attack subsides. For the other indications, the recommended starting dose is 500 mg followed by 250 mg every 6 to 8 hours as required, not to exceed 1250 mg per day.

**At plasma pH**, naproxen exists predominantly as the naproxen ion that reversibly binds the enzyme cyclooxygenase and inhibits prostaglandin synthesis, affecting conditions where overproduction of prostaglandins occurs. Other mechanisms of action may be possible. Due to possible cross-reactivity, naproxen is contraindicated in patients in whom aspirin or other NSAID agents induce the syndrome of asthma, rhinitis, and nasal polyps, and in patients who have had any symptoms of allergic reactions to NSAIDs. The major adverse reaction is gastrointestinal irritation, upset, and dyspepsia, but serious gastrointestinal toxicity (ulceration, bleeding, and perforation) can occur with chronic use.

**Pharmacokinetics**— Naproxen is rapidly and completely absorbed following oral administration with a reported time of maximum concentration (T<sub>max</sub>) values of 2 hours and 2 to 4 hours. Because naproxen is insoluble in water at low pH but freely soluble at physiologic pH, the rate of gastric emptying and pH of the gastric and intestinal contents are more likely to be rate-limiting for naproxen absorption than dissolution in gastrointestinal fluids. After single oral doses of 100, 200, and 300 mg, reported maximum concentrations (C<sub>max</sub>) values were 12, 25, and 42 µg per mL, respectively. A 500-mg dose produces a C<sub>max</sub> of about 55 µg per mL. Food may delay absorption by decreasing the rate of gastric emptying, but does not significantly change C<sub>max</sub> or area under the plasma concentration-time curve (AUC). In general, the advantages of reduced gastrointestinal irritation are thought to outweigh any clinical effects of slowed absorption rate.

The volume of distribution of naproxen is about 0.09 to 0.16 L per kg. The drug distributes into synovial fluid to reach about 50% of plasma levels 3 to 4 hours after dosing. Naproxen is ≥ 99% bound to plasma proteins (albumin), and this binding is known to decrease with increasing plasma drug concentrations (99.6% bound at total plasma concentrations of 23 to 40 µg per mL; 97.4% bound at 473 µg per mL). Disproportional increments in naproxen AUC at doses >500 mg per day are attributed to nonlinear plasma protein binding. For this poorly extracted drug, the increased free fraction of naproxen at higher doses results in more unbound naproxen available for biotransformation and urinary excretion. Despite nonlinear disposition, the half-life of naproxen is independent of dosage or plasma concentration after both single or multiple doses; reported values are 12 to 16 hours. In humans, naproxen is metabolized to naproxen glucuronide (40%), an unknown conjugate (20%), and 6-desmethylnaproxen (28%). The latter moiety is itself conjugated with glucuronide (12%). Less than 10% of naproxen is excreted unchanged in the urine. About 95% of a dose appears in the urine after 5 days, with less than 5% fecal excretion.

#### in vivo bioequivalence studies<sup>5</sup>

##### Product Information—

FDA Designated Reference Product: Naprosyn® (Syntex) 500-mg tablet.

**Batch Size**— The test batch or lot must be manufactured under production conditions and must be of a size that is at least 10% that of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.

**Potency**— The assayed potency of the reference product should not differ from that of the test product by more than 5%.

#### Types of Studies Required—

1. A single-dose, randomized, two-period, two-treatment, two-sequence crossover study under fasting conditions comparing equal doses of the test and reference products.
2. A single-dose, randomized, three-treatment, three-period, six-sequence crossover, limited food effects study comparing equal doses of the test and reference products when administered immediately following a standard high-fat breakfast.<sup>6</sup>

#### Recommended Protocol for Conducting a Single-Dose Bioequivalence Study under Fasting Conditions—

**Objective**— The objective is to compare the rate and extent of absorption of a generic formulation with that from a reference formulation when given as equal labeled doses.

**Design**— The study design is a single-dose, two-treatment, two-period, two-sequence crossover with a 1-week washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to each of the 2 possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

**Facilities**— The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

**Selection of Subjects**— The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 24 subjects be used in this study. Subjects should preferably be healthy, preferably nonsmoking, volunteers aged 18 to 55 within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). If smokers are included, they should be identified as such. Subjects should be selected on the basis of acceptable medical history, physical examination, and clinical laboratory test results. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. Written, informed consent must be obtained from all study participants before they are accepted into the study.

**Procedure**— Following an overnight fast of at least 10 hours, subjects should be administered a single 500-mg tablet of the test or reference product with 240 mL of water.

**Restrictions**— Study volunteers should observe the following restrictions:

- a. Water may be taken except for 1 hour before and after drug administration when no liquid is allowed other than that needed for drug dosing.
- b. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- c. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- d. Subjects should take no Rx medications, including oral contraceptives, beginning 2 weeks and no OTC medications beginning 1 week before drug administration and until after the study is completed.

...od Sampling—Venous blood samples should be collected pre-dose (0 hours) and at 0.50, 1, 1.5, 2, 2.5, 3, 3.5, 4, 6, 8, 12, 18, 24, 36, 48, and 72 hours post-dose. Plasma should be separated promptly and immediately frozen until assayed. Following a minimum 1-week washout period, subjects should begin the second phase of the study.

Subject Monitoring—Blood pressure and pulse rate should be monitored hourly during the first 4 hours of the study. Subjects with a heart rate less than 45 bpm or greater than 110 bpm should have an electrocardiogram (lead II) performed and have their pulse monitored hourly. Subjects should report any unusual symptoms observed during the study. Subjects should be periodically questioned during each phase of the study for any unusual symptoms experienced after drug administration.

Analytical Methods—Naproxen should be assayed using a suitable method fully validated with respect to adequate sensitivity, specificity, linearity, recovery, accuracy, and precision (both within and between days). Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined. Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

Statistical Analysis of Pharmacokinetic Data—See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances.

#### Limited Food Effects Study—

Objective—The objective is to compare the rate and extent of absorption of naproxen from a generic formulation with that from a reference formulation under nonfasting conditions and to compare the rate and extent of absorption of the drug from a generic formulation under fasting and nonfasting conditions when given as equal labeled doses.

Design—The study design is a single-dose, three-treatment, three-period, six-sequence crossover with a 1-week washout period between Phase I and Phase II, and Phase II and Phase III. An equal number of subjects should be assigned to each of the 6 dosing sequences.

The limited food effects study should be performed in the same manner as the single-dose study under fasting conditions, with the following exceptions:

Procedure—An equal number of subjects should be assigned to each of the 6 dosing sequences possible in a three-treatment, three-period study design (minimum 12 subjects). Each subject will receive the following treatments:

TREATMENT 1: Generic product, a 500-mg tablet administered after a standard high-fat breakfast.

TREATMENT 2: Reference product, a 500-mg Naprosyn® tablet (Syntex) administered after a standard high-fat breakfast.

TREATMENT 3: Generic product, a 500-mg tablet administered under fasting conditions.

Following a 10-hour fast, the subjects receiving treatments under fed conditions should be served a standard high-fat breakfast. The subjects should have 30 minutes to finish the entire breakfast and then should immediately receive Treatment 1 or Treatment 2, taken with 240 mL of water. Subjects receiving the treatment under fasting conditions should receive Treatment 3, taken with 240 mL of water only. The same lots of the test and reference products should be used in the fasted and fed studies. No food should be allowed for at least 4 hours post-dose, with water allowed after the first hour. Subjects should be served scheduled standardized meals throughout the study, and the same meals should be served during all phases of the study.

Statistical Analysis—In general, a comparable food effect will be assumed if the AUC<sub>0-t</sub>, AUC<sub>0-</sub>, C<sub>max</sub> mean values for the test product administered under fed conditions are within 20% of the respective mean values obtained for the reference product administered under fed conditions.

Clinical Report, Side Effects, and Adverse Reactions—Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions and side effects to the study formulations should be reported.

Retention of Samples—The laboratory conducting the bioequivalence testing should retain appropriately identified reserve samples of both the test and reference products used to perform the *in vivo* bioequivalence studies for approval of the application. Each reserve sample should consist of at least 200 dosage units or 5 times the amount needed for complete release testing and should be retained for a minimum of 5 years following approval of the application. For more information on retention of bioequivalence samples refer to 21 CFR 320.63.

#### in vitro testing requirements

Dissolution Testing—Conduct dissolution testing on 12 dosage units of the test product and the reference product, employing the biostudy lots. The current official USP dissolution method (see [Dissolution](#) 711) should be followed and should be referenced by the sponsor. The following times should be used to determine the dissolution profile. Times: 10, 20 30, 45, and 60 minutes.

The percentage of label claim dissolved at each specified testing interval should be reported for each individual dosage unit. The mean percentage dissolved, the range (highest, lowest) of dissolution, and the coefficient of variation (relative standard deviation) should be reported.

Content Uniformity Test—Content uniformity testing on the test and reference product lots should be performed as described in USP.

#### waiver requirements

Waiver of *in vivo* bioequivalence study requirements for the 375- and 250-mg strengths of the generic product may be granted pursuant to 21 CFR 320.22(d)(2) provided the following conditions are met:

1. The 375- and 250-mg tablets are proportionally similar in both active and inactive ingredients to the firm's 500-mg tablet, which has been demonstrated to be bioequivalent to the reference product *in vivo*.
2. The 375- and 250-mg tablets of the generic product meet dissolution test requirements.

#### Pentoxifylline Extended-Release Tablets—*In Vivo* Bioequivalence and *In Vitro* Dissolution Testing<sup>4</sup>

Clinical Usage/Pharmacology—Pentoxifylline is a hemorrhheologic agent that improves the flow properties of blood by decreasing its viscosity and improving erythrocyte flexibility. These actions increase blood flow and enhance tissue oxygenation in patients with chronic peripheral arterial disease. It is indicated for the treatment of patients with intermittent claudication on the basis of chronic occlusive arterial disease of the limbs. The usual dosage is one tablet three times a day with meals.

Pharmacokinetics—Urinary recovery data suggests virtually complete absorption of pentoxifylline from the extended-release dosage form. The absolute bioavailability at steady state (every 8 hours for 6 days) is estimated to be 19.4%, indicating extensive first-pass metabolism. Pentoxifylline undergoes both oxidation and reduction metabolism with greater than 90% of a dose being eliminated renally as metabolites. Both pentoxifylline and its reduction metabolite 1-(5-hydroxyhexyl)-3,7-dimethylxanthine (M1) and its oxidation metabolite 1-(3-carboxypropyl)-3,7-dimethylxanthine (M5) have similar pharmacological effects.

Administration of single doses of 400-mg pentoxifylline extended-release tablets results in T<sub>max</sub> values of 2 to 4 hours and mean C<sub>max</sub> values of 55 to 300 ng per mL. The apparent mean half-life of the parent drug is about 3.4 hours, demonstrating the absorption-limited elimination rate of the extended-release dosage form. After multiple dosing of pentoxifylline extended-release tablets (400 mg every 8 hours for 6 to 7 days), mean steady-state values of pentoxifylline C<sub>max</sub> were 189 to 248 ng per mL and T<sub>max</sub> was 0.9 to 2 hours. Reported mean values for M1 (400-mg extended-release tablet) from single-dose studies are as follows: C<sub>max</sub>, 143 to 343 ng per mL; T<sub>max</sub>, 3.2 hours; and t<sub>1/2</sub>, 3.4 hours. Mean steady-state values for M1 from multiple-dose studies were reported as follows: C<sub>max</sub>, 562 to 576 ng per mL; and T<sub>max</sub>, 2 to 2.8 hours. For M5, the corresponding values were 943 ng per mL and 1.4 hours, respectively. Drug absorption is slower when pentoxifylline is taken with food resulting in a significant decrease in C<sub>max</sub> and increase in T<sub>max</sub> for parent drug and metabolites. However, AUC is not changed significantly.

#### in vivo bioequivalence studies<sup>5</sup>

##### Product Information—

FDA Designated Reference Product: Trental® (Hoechst Marion Roussel) 400-mg extended-release tablets.

Batch Size—The test batch or lot must be manufactured under production conditions and must be of a size that is at least 10% of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.

Potency— The assayed potency of the reference product should not differ from that of the test product by more than 5%.

Types of Studies Required—

1. A single-dose, randomized, two-treatment, two-period, two-sequence crossover study under fasting conditions comparing equal doses of the test and reference products.
2. A multiple-dose, steady-state, randomized, two-treatment, two-period, two-sequence crossover study under fasting conditions comparing equal doses of the test and reference products.
3. A single-dose, randomized, three-treatment, three-period, six-sequence crossover, limited food effects study comparing equal doses of the test and reference products when administered immediately following a standard high-fat breakfast.<sup>6</sup>

Recommended Protocol for Conducting a Single-Dose Bioequivalence Study under Fasting Conditions—

Objective— The objective is to compare the rate and extent of absorption of a generic formulation with that of the reference formulation when given as equal labeled doses.

Design— The study design is a single dose, two-treatment, two-period, two-sequence crossover with a 1-week washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to each of the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

Facilities— The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

Selection of Subjects— The sponsors should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 24 subjects be used in this study. Subjects should be healthy, preferably nonsmoking, volunteers aged 18 to 50 years and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of acceptable medical history, physical examination, and clinical laboratory test results. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. Female subjects must be given a pregnancy test prior to beginning the study. If smokers are included, they should be identified as such. Written, informed consent must be obtained from all study participants before they are accepted into the study.

Procedure— Following an overnight fast of at least 10 hours, subjects should be administered a single dose of the test or reference product with 240 mL of water.

Restrictions— Study volunteers should observe the following restrictions:

- a. Water may be taken, except for 1 hour before and after drug administration when no liquid is allowed other than that needed for drug dosing.
- b. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- c. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- d. Subjects should take no Rx medications, including oral contraceptives, beginning 2 weeks and no OTC medications beginning 1 week before drug administration and until after the study is completed.

Blood Sampling— Venous blood samples should be collected pre-dose (0 hours) and at 0.5, 0.75, 1, 1.5, 2, 2.5, 3, 3.5, 4, 4.5, 5, 6, 8, 10, 12, 16, 24, and 30 hours post-dose. Plasma or serum should be separated promptly and immediately frozen until assayed. Following a 1-week washout period, subjects should begin the second phase of the study.

Subject Monitoring— Blood pressure and pulse rate should be monitored hourly during the first 4 hours of the study. Subjects with a heart rate less than 45 bpm or greater than 110 bpm should have an electrocardiogram (lead II) performed and have their pulse monitored hourly. Subjects should report any unusual symptoms observed during the study. Subjects should be periodically questioned during each phase of the study for any unusual symptoms experienced after drug administration.

Analytical Methods— Pentoxyline and two of its active metabolites 1-(5-hydroxyhexyl)-3,7-dimethylxanthine (M1) and 1-(3-carboxypropyl)-3,7-dimethylxanthine (M5) should be assayed using a suitable method fully validated with respect to adequate sensitivity, specificity, linearity, recovery, and accuracy and precision (both within and between days). Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined. Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

Statistical Analysis of Pharmacokinetic Data— See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances.

Recommended Protocol for Conducting a Multiple-Dose, Steady-State, Bioequivalence Study under Fasting Conditions—

Objective— The objective is to compare the steady-state rate and extent of absorption of a generic extended-release pentoxyline formulation with that of the reference formulation when given as equal labeled doses.

Design— The study design is a multiple-dose, steady-state, two-treatment, two-period, two-sequence crossover with a 1-week washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to the two possible dosing sequences. Before the study begins, the proposed protocols should be approved by an institutional review board.

The multiple-dose, steady-state, bioequivalence study should be performed in the same manner as directed under Recommended Protocol for Conducting a Single-Dose Bioequivalence Study under Fasting Conditions, with the following exceptions:

Procedure— Subjects should begin a regimen in which consecutive doses of the test or reference products are given every 8 hours with 240 mL of water until steady-state blood serum and plasma levels are attained by all. After reaching steady state, subjects should be administered the final dose of the test or the reference product with 240 mL of water at the next dosing interval.

Restrictions— Item "b" should state: Meals should be scheduled at least 2 hours post-dose for all doses. After the final dose of each treatment is administered and intensive sampling begins, fasting should be continued for 4 hours. All meals should be standardized during the study, and the same meals should be served during both phases of the study.

Blood Sampling— The pre-dose blood sampling must include at least three trough level samples on three consecutive days (collected at the same time of day) to demonstrate that steady-state blood plasma and serum levels are achieved prior to the final Phase I dose. Adequate blood samples should be collected at appropriate times during a dosing interval at a steady state to permit estimation of AUCinterdose. Additional samples should then be collected to permit estimation of the terminal elimination rate constant  $\lambda_{z}$ . Following a 1-week washout period, subjects should begin the second phase of the study.

Limited Food Effects Study—

Objective— The objective is to compare the rate and extent of absorption of pentoxyline from a generic formulation with that from a reference formulation under nonfasting conditions and to compare the rate and extent of absorption of the drug from a generic formulation under fasting and nonfasting conditions when given as equal labeled doses.

Design— The study design is a single-dose, randomized, three-treatment, three-period, six-sequence crossover with a 1-week washout period between Phase I and Phase II, and Phase II and Phase III. An equal number of subjects should be assigned to each of the six dosing sequences.

The limited food effects study should be performed in the same manner as directed under Recommended Protocol for Conducting a Single-Dose Bioequivalence Study under Fasting Conditions, with the following exceptions:

Procedure— An equal number of subjects should be assigned to each of the six dosing sequences possible in a three-treatment, three-period study design (minimum 18 subjects).

Each subject will receive the following treatments:

TREATMENT 1: Generic product, a 400-mg extended-release pentoxyline tablet administered after a standard high-fat breakfast.

TREATMENT 2: Reference product, a 400-mg extended-release Trental® tablet administered after a standard high-fat breakfast.

TREATMENT 3: Generic product, a 400-mg extended-release pentoxyline tablet administered under fasting conditions.

following a 10-hour fast, the subjects receiving treatments under nonfasting conditions should be served a standard high-fat breakfast. The subjects should have 30 minutes to finish the entire breakfast, then should immediately receive Treatment 1 or Treatment 2, taken with 240 mL of water. Subjects receiving treatment under fasting conditions should receive Treatment 3, taken with 240 mL of water only. The same lots of the test and reference products should be used in the fasting and nonfasting studies. No food should be allowed for at least 4 hours post-dose, with water allowed after the first hour. Subjects should be served scheduled standardized meals throughout the study, and the same meals should be served during all phases of the study.

**Statistical Analysis**— In general, a comparable food effect will be assumed if the AUC<sub>0-t</sub>, AUC<sub>0-∞</sub>, and C<sub>max</sub> mean values for the test product administered under nonfasting conditions are within 20% of the respective mean values obtained for the reference product administered under nonfasting conditions.

**Clinical Report, Side Effects, and Adverse Reactions**— Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions to the study formulations should be reported.

**Retention of Samples**— The laboratory conducting the bioequivalence testing should retain appropriately identified reserve samples of both the test and reference product used to perform the *in vivo* bioequivalence studies for approval of the application. Each reserve sample should consist of at least 200 dosage units or 5 times the amount needed for complete release testing and should be retained for a minimum of 5 years following approval of the application. For more information on retention of bioequivalence samples, refer to 21 CFR 320.63.

#### in vitro testing requirements

**Drug Release Testing** (724) — Drug release testing should be conducted on 12 individual dosage units of batches of the test and reference products employing the biostudy lots. The potential for pH dependence of drug release from an extended-release product is well recognized. Drug release profiles should, therefore, be generated in aqueous media at the following pH ranges: 1–1.5, 4–4.5, and 6.0–6.8. See *In Vitro Drug Release for Quality Control Preapproval under General Guidances*. The following times should be used to determine the drug release profile.

Times: 1, 2, and 4 hours and every 2 hours until 80% of drug is released.

The percentage of label claim dissolved at each specified testing interval should be reported for each individual dosage unit. The mean percentage dissolved, the range (highest, lowest) of dissolution, and the coefficient of variation (relative standard deviation) should be reported.

**Content Uniformity Test** (905) — Content uniformity testing on the test and reference product lots should be performed as described in USP.

#### Pindolol Tablets—*In Vivo* Bioequivalence and *In Vitro* Dissolution Testing<sup>4</sup>

**Clinical Pharmacology/Usage**— Pindolol is a nonselective beta-adrenergic antagonist with intrinsic sympathomimetic activity in therapeutic dosage ranges. Pindolol has low membrane stabilizing activity. The drug is indicated for the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide type diuretic.

In the management of hypertension, the recommended initial dose is 5 mg twice a day administered alone or in combination with other antihypertensives. The dosage may be adjusted in increments of 10 mg per day, up to a maximum dosage of 60 mg per day.

**Pharmacokinetics**— Following intravenous administration of pindolol, the plasma concentration-time data can be described by a biexponential equation. The disposition of pindolol after oral administration has also been reported to be monophasic with an elimination half-life of approximately 3 to 4 hours in healthy subjects or hypertensive patients with normal renal function.

Pindolol is rapidly absorbed, achieving peak plasma concentrations within 1 to 2 hours of drug administration. It has a stated bioavailability of greater than 95%. Earlier studies also reported oral bioavailability of 90% to 100%. One study, however, reported an oral absolute bioavailability of only 53%. The bioavailability of pindolol is not significantly affected by co-administration with food. Food, however, increases the rate of absorption. Pindolol has a negligible first-pass effect. The blood concentrations are linearly proportional to the administered dose in the range of 5 to 20 mg.

The lipid solubility of pindolol is considered intermediate in comparison with other beta blockers. The apparent volume of distribution has been reported to be 1.2 to 2 L per kg. Pindolol is about 40% to 60% bound to plasma proteins and is evenly distributed between plasma and red cells.

Approximately 35% to 40% of the administered dose is excreted unchanged in the urine and 60% to 65% is metabolized, primarily to hydroxy-metabolites, which are excreted as glucuronides and ether sulfates. The polar metabolites are excreted with a half-life of approximately 8 hours. About 6% to 9% of an administered intravenous dose is excreted from the bile into the feces.

#### in vivo bioequivalence studies<sup>5</sup>

##### Product Information—

FDA Designated Reference Product: Visken® (Sandoz) 10-mg tablet.

**Batch Size**— The test batch or lot must be manufactured under production conditions and must be of a size that is at least 10% that of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.

**Potency**— The assayed potency of the reference product should not differ from that of the test product by more than 5%.

**Type of Study Required**— A single-dose, randomized, two-period, two-treatment, two-sequence crossover study under fasting conditions comparing equal doses of the test and reference products.

##### Recommended Protocol for Conducting a Single-Dose Study under Fasting Conditions—

**Objective**— The objective is to compare the rate and extent of absorption of pindolol from a generic formulation with that of a reference formulation when given as equal labeled doses.

**Design**— The study design is a single-dose, two-treatment, two-period, two-sequence crossover with a 1-week washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to each of the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

**Facilities**— The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

**Selection of Subjects**— The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 24 subjects be used in this study. Subjects should be healthy nonsmoking volunteers aged 18 to 50 and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of acceptable medical history, physical examination, and clinical laboratory test results. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. Written, informed consent must be obtained from all study participants before they are accepted into the study.

**Procedure**— Following an overnight fast of at least 10 hours, subjects should be administered two 10-mg tablets of the test or reference product with 240 mL of water.

**Restrictions**— Study volunteers should observe the following restrictions:

- a. Water may be taken except for 1 hour before and after drug administration when no liquid is allowed other than that needed for drug dosing.
- b. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- c. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- d. Subjects should take no Rx medications, including oral contraceptives, beginning 2 weeks and no OTC medications beginning 1 week before drug administration and until after

the study is completed.

Blood Sampling— Venous blood samples should be collected pre-dose (0 hours) and at 0.25, 0.50, 0.75, 1, 1.50, 2, 3, 4, 6, 8, 10, 12, 16, and 24 hours post-dose. Plasma or serum should be separated promptly and immediately frozen until assayed. Following a minimum 1-week washout period, subjects should begin the second phase of the study.

Subject Monitoring— Blood pressure and pulse rate should be monitored hourly during the first 4 hours of the study. Subjects with a heart rate less than 45 bpm or greater than 110 bpm should have an electrocardiogram (lead II) performed and have their pulse monitored hourly. Subjects should report any unusual symptoms observed during the study. Subjects should be periodically questioned during each phase of the study for any unusual symptoms experienced after drug administration.

Analytical Methods— Pindolol should be assayed using a suitable method fully validated with respect to adequate sensitivity, specificity, linearity, recovery, accuracy, and precision (both within and between days). Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined.

Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

Statistical Analysis of Pharmacokinetic Data— See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances.

Clinical Report, Side Effects, and Adverse Reactions— Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions and side effects to the study formulations should be reported.

Retention of Samples— The laboratory conducting the bioequivalence testing should retain appropriately identified reserve samples of both the test and reference products used to perform the in vivo bioequivalence studies for approval of the application. Each reserve sample should consist of at least 200 dosage units or 5 times the amount needed for complete release testing and should be retained for a minimum of 5 years following approval of the application. For more information on retention of bioequivalence samples, refer to 21 CFR 320.63.

#### in vitro testing requirements

Dissolution Testing— Conduct dissolution testing on 12 dosage units of the test product versus 12 units of the reference product. The biostudy lots should be used for those product strengths tested in vivo. The current official USP dissolution method (see [Dissolution](#) 711) should be followed and should be referenced by the sponsor. The following method and tolerances are currently recommended for this product:

Medium: 0.1 N hydrochloric acid; 500 mL.

Apparatus 2: 50 rpm.

Times: 5, 10, and 15 minutes.

Procedure— Use USP if available, or other validated method (see [Validation of Compendial Procedures](#) 1225).

Tolerance (Q): not less than 80% in 15 minutes.

The percentage of label claim dissolved at each specified testing interval should be reported for each individual dosage unit. The mean percentage dissolved, the range (highest, lowest) of dissolution, and the coefficient of variation (relative standard deviation) should be reported.

Content Uniformity Test— Content uniformity testing on the test and reference product lots should be performed as described in USP.

#### waiver requirements

Waiver of in vivo bioequivalence study requirements for the 5-mg strength of the generic product may be granted pursuant to 21 CFR 320.22(d)(2), provided the following conditions are met:

1. The 5-mg tablet is proportionally similar in both active and inactive ingredients to the firm's 10-mg tablet, which has been demonstrated to be bioequivalent to the reference product in vivo.
2. The 5-mg tablet of the generic product meets dissolution test requirements.

#### Piroxicam Capsules—In Vivo Bioequivalence and In Vitro Dissolution Testing<sup>4</sup>

Clinical Pharmacology/Usage— Piroxicam is a nonsteroidal anti-inflammatory drug (NSAID). It is indicated for acute or long-term use in the relief of signs and symptoms of osteoarthritis and rheumatoid arthritis. It is recommended that a single 20-mg dose be given daily for these conditions. The daily dose may be divided into two 10-mg capsules.

Like other nonsteroidal anti-inflammatory drugs, piroxicam inhibits prostaglandin synthesis by blocking cyclooxygenase; it has no effect on lipoxygenase. Piroxicam has been reported to have a greater effect than other nonsteroidal anti-inflammatory drugs in inhibiting rheumatoid factor production, in increasing phytohemagglutinin response, and in increasing the percentage of suppressor T-cells in peripheral blood. The significance of these effects on its anti-inflammatory and antiarthritic action is not clear.

Piroxicam should not be used in patients with the syndrome comprised of bronchospasm, nasal polyps, and angioedema precipitated by aspirin or other NSAIDs. The major adverse reaction associated with piroxicam is GI irritation.

Pharmacokinetics— Following oral administration, piroxicam is rapidly absorbed. Peak plasma levels occur in 2 to 5 hours with a terminal elimination half-life ranging between 30 and 60 hours. Two or more peaks are usually observed in the piroxicam plasma concentration-time profile between 3 and 12 hours after dosing. Enterohepatic recirculation of piroxicam has been cited as the possible explanation for these multiple peaks. However, a preliminary study in healthy volunteers did not reveal any biliary secretion of piroxicam. The prolonged half-life of piroxicam results in the maintenance of relatively stable plasma concentrations throughout the day on a once daily regimen. With repeated daily doses of 20 mg, steady-state plasma levels of 3 to 5 µg per mL are attained in 7 to 12 days.

Piroxicam is extensively bound (99%) to plasma proteins. Despite very high plasma binding, piroxicam readily penetrates into the synovial fluid of patients with rheumatoid arthritis, osteoarthritis, and reactive synovitis, where piroxicam concentrations are about 40% of those in plasma. This concentration difference of unbound piroxicam across the synovial membrane may be explained by ion trapping of piroxicam in plasma, assuming a pH for synovial fluid significantly lower than 7.4. The very high plasma binding of piroxicam limits its distribution mainly to extracellular space. As a result, the Vd of piroxicam is small, usually about 0.14 L per kg, which is a value typical for most NSAIDs.

Piroxicam is eliminated mainly by biotransformation with less than 5% of the dose excreted unchanged in urine. Hydroxylation and subsequent conjugation with glucuronic acid is the major metabolic pathway in man. This piroxicam metabolite has little or no anti-inflammatory activity.

#### in vivo bioequivalence studies<sup>5</sup>

##### Product Information—

FDA Designated Reference Product: Feldene® (Pfizer Co.) 20-mg capsules.

Batch Size— The test batch or lot must be manufactured under production conditions and must be of a size that is at least 10% that of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.

Potency— The assayed potency of the reference product should not differ from that of the test product by more than 5%.

#### Types of Studies Required—

1. A single-dose, randomized, two-period, two-treatment, two-sequence crossover study under fasting conditions comparing equal doses of the test and reference products.
2. A single-dose, randomized, three-treatment, three-period, six-sequence crossover, limited food effects study comparing equal doses of the test and reference products when administered immediately following a standard high-fat breakfast.<sup>6</sup>

#### Recommended Protocol for Conducting a Single-Dose, Fasted Bioequivalence Study—

**Objective**— The objective is to compare the rate and extent of absorption of a generic formulation with that of a reference formulation when given as equal labeled doses.

**Design**— The study design is a single-dose, two-treatment, two-period, two-sequence crossover with a 2-week washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to each of the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

**Facilities**— The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

**Selection of Subjects**— The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 24 subjects be used in this study. Subjects should be healthy, preferably nonsmoking, volunteers aged 18 to 55 and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of acceptable medical history, physical examination, and clinical laboratory test results. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. If smokers are included, they should be identified as such. Written, informed consent must be obtained from all study participants before they are accepted into the study.

**Procedure**— Following an overnight fast of at least 10 hours, subjects should be administered a single dose (20-mg) of the test or reference product with 240 mL of water.

#### Restrictions— Study volunteers should observe the following restrictions:

- a. Water may be taken except for 1 hour before and after drug administration when no liquid is allowed other than that needed for drug dosing.
- b. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- c. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- d. Subjects should take no Rx medications, including oral contraceptives, beginning 2 weeks and no OTC medications beginning 1 week before drug administration and until after the study is completed.

**Blood Sampling**— Venous blood samples should be collected pre-dose (0 hours) and at 0.5, 1, 1.5, 2, 2.5, 3, 4, 5, 6, 8, 10, 12, 14, 16, 18, 24, 36, 48, 72, 96, 120, 144, and 168 hours post-dose. Plasma should be separated promptly and immediately frozen until assayed. Following a minimum 2-week washout period, subjects should begin the second phase of the study.

**Subject Monitoring**— Blood pressure and pulse rate should be monitored hourly during the first 4 hours of the study. Subjects with a heart rate less than 45 bpm or greater than 110 bpm should have an electrocardiogram (lead II) performed and have their pulse monitored hourly. Subjects should report any unusual symptoms observed during the study. Subjects should be periodically questioned during each phase of the study for any unusual symptoms experienced after drug administration.

**Analytical Methods**— Piroxicam should be assayed using a suitable method fully validated with respect to adequate sensitivity, specificity, linearity, recovery, accuracy, and precision (both within and between days). Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined.

Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

**Statistical Analysis of Pharmacokinetic Data**— See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances.

#### Limited Food Effects Study—

**Objective**— The objective is to compare the rate and extent of absorption of piroxicam from a generic formulation with that from a reference formulation under nonfasting conditions and to compare the rate and extent of absorption of the drug from a generic formulation under fasting and nonfasting conditions when given as equal labeled doses.

**Design**— The study design is a single-dose, three-treatment, three-period, six-sequence crossover with a 2-week washout period between Phase I and Phase II, and Phase II and Phase III. An equal number of subjects should be assigned to each of the 6 dosing sequences.

The limited food effects study should be performed in the same manner as the single-dose study under fasting conditions, with the following exceptions:

**Procedure**— An equal number of subjects should be assigned to each of the 6 dosing sequences possible in a three-treatment, three-period study design (minimum 12 subjects). Each subject will receive the following treatments:

TREATMENT 1: Generic product, a 20-mg capsule administered after a standard high-fat breakfast.

TREATMENT 2: Reference product, a 20-mg Feldene® capsule (Pfizer) administered after a standard high-fat breakfast.

TREATMENT 3: Generic product, a 20-mg capsule administered under fasting conditions.

Following a 10-hour fast, the subjects receiving treatments under fed conditions should be served a standard high-fat breakfast. The subjects should have 30 minutes to finish the entire breakfast and then should immediately receive Treatment 1 or Treatment 2, taken with 240 mL of water. Subjects receiving the treatment under fasting conditions should receive Treatment 3, taken with 240 mL of water only. The same lots of the test and reference products should be used in the fasted and fed studies. No food should be allowed for at least 4 hours post-dose with water allowed after the first hour. Subjects should be served scheduled standardized meals throughout the study, and the same meals should be served during all phases of the study.

**Statistical Analysis**— In general, a comparable food effect will be assumed if the AUC<sub>0-t</sub>, AUC<sub>0-∞</sub>, and C<sub>max</sub> mean values for the test product administered under fed conditions are within 20% of the respective mean values obtained for the reference product administered under fed conditions.

**Clinical Report, Side Effects, and Adverse Reactions**— Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions and side effects to the study formulations should be reported.

**Retention of Samples**— The laboratory conducting the bioequivalence testing should retain appropriately identified reserve samples of both the test and reference products used to perform the in vivo bioequivalence studies for approval of the application. Each reserve sample should consist of at least 200 dosage units or 5 times the amount needed for complete release testing and should be retained for a minimum of 5 years following approval of the application. For more information on retention of bioequivalence samples refer to 21 CFR 320.63.

#### in vitro testing requirements

**Dissolution Testing**— Conduct dissolution testing on 12 dosage units of the test product and the reference product, employing the biostudy lots. The current official USP dissolution method (see [Dissolution](#) (711)) should be followed and should be referenced by the sponsor. The following times should be used to determine the dissolution profile: Times: 15, 30, 45, and 60 minutes.

The percentage of label claim dissolved at each specified testing interval should be reported for each individual dosage unit. The mean percentage dissolved, the range (highest, lowest) of dissolution, and the coefficient of variation (relative standard deviation) should be reported.

**Content Uniformity Test**— Content uniformity testing on the test and reference product lots should be performed as described in USP.

#### waiver requirements

Waiver of in vivo bioequivalence study requirements for the 10-mg capsule of the generic product may be granted pursuant to 21 CFR 320.22(d)(2) provided the following conditions are met:

1. The 10-mg capsule is proportionally similar in both active and inactive ingredients to the firm's 20-mg capsule, which has been demonstrated to be bioequivalent to the reference product *in vivo*.

2. The 10-mg capsule of the generic product meets dissolution test requirements.

#### Ranitidine Hydrochloride Tablets—In Vivo Bioequivalence and In Vitro Dissolution Testing<sup>4</sup>

**Clinical Usage/Pharmacology**— Ranitidine hydrochloride is a histamine H<sub>2</sub>-receptor antagonist, which inhibits competitively and reversibly the interaction of histamine with H<sub>2</sub>-receptors. It reduces gastric acid secretion elicited by histamine and gastrin and stimulated by betazole and food. Ranitidine hydrochloride also inhibits basal and nocturnal acid secretion.

Ranitidine hydrochloride is indicated in active and maintenance therapies of duodenal ulcer. It is also used in treatments of active, benign gastric ulcer, pathological hypersecretory conditions, and gastroesophageal reflux disease. Serum concentrations of 36 to 94 ng per mL of ranitidine hydrochloride have been shown to inhibit 50% of stimulated gastric acid secretion. The recommended oral dosage of ranitidine hydrochloride tablets for active duodenal ulcer is 150 mg twice a day, or 300 mg at bedtime.

**Pharmacokinetics**— An absolute oral bioavailability of 50% has been reported for 150-mg ranitidine hydrochloride tablets. Mean values of 60% and 52% have also been reported as the absolute bioavailability of two other formulations of 150- and 100-mg ranitidine hydrochloride tablets, respectively.

A linear relationship has been found between the dose and the area under the serum concentration-time curve following the administration of oral doses of 100, 150, 250, and 400 mg of ranitidine hydrochloride tablets.

A secondary peak in the plasma concentration-time curve has been reported for ranitidine hydrochloride following oral administration of 100- and 150-mg tablets in fasting studies. The mean values reported for the peaks were 1.5 hours for the first peak and 3.9 hours for the second.

The reported elimination half-life of ranitidine hydrochloride is 2.5 to 3.0 hours. Approximately 30% of ranitidine hydrochloride is excreted unchanged in urine within 24 hours following the administration of an oral dose. The major urinary metabolite of ranitidine hydrochloride in man is N-oxide, which represents less than 4% of the dose. S-oxide (1%) and desmethyl ranitidine (1%) are the other metabolites of ranitidine hydrochloride.

Multiple-dose studies in which ranitidine hydrochloride was administered in doses of 150 and 200 mg twice daily for 28 days showed that ranitidine hydrochloride did not accumulate in the body, and the values of the pharmacokinetic parameters were similar for both single- and multiple-dose studies.

Administration of food or antacid reportedly does not change the absorption of ranitidine hydrochloride tablets significantly. However, concomitant administration of high doses of antacids with the 150-mg tablets reduced its absorption.

#### in vivo bioequivalence studies<sup>5</sup>

##### Product Information—

FDA Designated Reference Product: Zantac® (Glaxo) 300-mg tablets.

**Batch Size**— The test batch or lot must be manufactured under production conditions and must be of a size at least 10% that of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.

**Potency**— The assayed potency of the reference product should not differ from that of the test product by more than 5%.

**Type of Study Required**— A single-dose, randomized, two-period, two-treatment, two-sequence crossover study under fasting conditions comparing equal doses of the test and reference products.

#### Recommended Protocol for Conducting a Single-Dose, Fasted Bioequivalence Study—

**Objective**— The objective is to compare the rate and extent of absorption of a generic formulation of ranitidine hydrochloride tablet with that of a reference formulation when given as equal labeled doses.

**Design**— The study design is a single-dose, two-treatment, two-period, two-sequence crossover with a 1-week washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to each of the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

**Facilities**— The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

**Selection of Subjects**— The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 24 subjects be used in this study. Subjects should be healthy, preferably nonsmoking, volunteers 18 to 50 years of age and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of acceptable medical history, physical examination, and clinical laboratory test results. Female subjects must be given a pregnancy test prior to beginning the study and between Phase I and Phase II. Nursing mothers should be excluded from the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. If smokers are included, they should be identified as such. Written, informed consent must be obtained from all study participants before they are accepted into the studies.

**Procedure**— Following an overnight fast of at least 10 hours, subjects should be administered a single 300-mg tablet dose of the test or reference product with 240 mL of water.

#### Restrictions— Study volunteers should observe the following restrictions:

- Water may be taken except for 1 hour before and after drug administration, when no liquid is allowed other than that needed for drug dosing.
- Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- Subjects should take no Rx medications, including oral contraceptives, beginning 2 weeks and no OTC medications beginning 1 week before drug administration and until after the study is completed.

**Blood Sampling**— Venous blood samples should be collected pre-dose (0 hours) and at 0.33, 0.50, 0.67, 1, 1.33, 1.50, 1.67, 2, 2.50, 3, 3.50, 4, 5, 6, 8, 10, 12, 16, and 24 hours post-dose. Plasma should be separated promptly and immediately frozen until assayed. Following a minimum 1-week washout period, subjects should begin the second phase of the study.

**Analytical Methods**— Ranitidine hydrochloride should be assayed using a suitable method fully validated with respect to adequate sensitivity, specificity, linearity, recovery, and accuracy and precision (both within and between days). Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined. Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

**Statistical Analysis of Pharmacokinetic Data**— See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances.

**Clinical Report, Side Effects, and Adverse Reactions**— Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions to the study formulations should be reported.

**Retention of Samples**— The laboratory conducting the bioequivalence testing should retain an appropriately identified reserve sample of both the test and reference products used to perform the in vivo bioequivalence study for approval of the application. Each reserve sample should consist of at least 200 dosage units and should be retained for a period of not less than 5 years following approval of the application. For more information on retention of bioequivalence samples, refer to 21 CFR 320.63.

#### in vitro testing requirements

**Dissolution Testing**— Conduct dissolution testing on 12 dosage units of the test product and the reference product, employing the biostudy lots. The current official USP dissolution method (see [Dissolution](#) 711) should be followed and should be referenced by the sponsor. The following method and tolerances are currently recommended for this product:

Medium: deaerated water; 900 mL.

Apparatus 2: 50 rpm.

Times: 10, 20, 30, and 45 minutes.

Procedure— Use USP if available, or other validated method (see [Validation of Compendial Procedures \(1225\)](#)).

Tolerances (Q): not less than 80% is dissolved in 45 minutes.

The percentage of label claim dissolved at each specified testing interval should be reported for each individual dosage unit. The mean percentage dissolved, the range (highest, lowest) of dissolution, and the coefficient of variation (relative standard deviation) should be reported.

Content Uniformity Test (905)— Content uniformity testing on the test product lots should be performed as described in USP.

waiver requirements

Waiver of in vivo bioequivalence study requirements for the 150-mg strength of the generic product may be granted pursuant to 21 CFR 320.22(d)(2) provided the following conditions are met:

1. The 150-mg tablet is proportionally similar in both active and inactive ingredients to the 300-mg tablet, which has been demonstrated to be bioequivalent to the reference product *in vivo*.
2. The 150-mg tablet of the generic product meets the dissolution testing requirements.

#### Selegiline Hydrochloride Tablets—*In Vivo* Bioequivalence and *In Vitro* Dissolution Testing<sup>4</sup>

**Clinical Usage/Pharmacology**— Selegiline hydrochloride is an irreversible inhibitor of monoamine oxidase (MAO) with greater affinity for MAO Type B (predominant form in the brain) compared to Type A (predominant intestinal form). Type A MAO is not inhibited by selegiline at therapeutic doses; therefore, the ability of MAO Type A (GI tract and liver) to prevent hypertensive effects from exogenous amines absorbed from the gut is not compromised. Selegiline can be used safely without dietary restrictions and with concomitant drug use only at doses that selectively inhibit MAO Type B ( $\leq$  10 mg per day). In addition to its inhibitory actions on MAO Type B, selegiline may also prevent indirect acting sympathomimetics from displacing norepinephrine from adrenergic neurons. By blocking the metabolism of dopamine in the brain, selegiline increases the amount of dopamine available to dopamine receptors that might be beneficial to treatment of Parkinsonism. Selegiline is indicated as an adjunct in the management of Parkinsonian patients being treated with levodopa and carbidopa who exhibit deterioration in the quality of their response to this therapy. Dosing is 10 mg per day; in an effort to minimize adverse effects, such as nausea and dizziness, that may follow a single 10-mg dose, divided doses of 5 mg are administered at breakfast and lunch.

**Pharmacokinetics**— Much of the original pharmacokinetic data reported for selegiline were obtained after administration of 14C-selegiline. The following results represent the total 14C-label (parent drug plus metabolites): 1) After oral administration of 5 mg 14C-selegiline, C<sub>max</sub> ranged from 33 to 45 ng per mL with a T<sub>max</sub> of 0.5 to 2 hours. 2) The elimination half-life of 14C-selegiline from plasma has been approximated at 39 hours (range, 16 to 69 hours). Of the three principal metabolites of selegiline—desmethylselegiline (DES), methamphetamine (MA), and amphetamine (A)—only DES is thought to contribute to the overall pharmacological effect. Due to a large volume of distribution and extensive first-pass metabolism, selegiline plasma concentrations after a 10-mg dose are difficult to detect. In a single-dose pilot study (N = 4) using this assay, the mean plasma elimination half-lives of selegiline and DES were 1.9 hours and 2.2 hours, respectively. The effects of food on selegiline absorption have not been reported.

*in vivo* bioequivalence studies<sup>5</sup>

Product Information—

FDA Designated Reference Product: Eldepryl® (Somerset) 5-mg tablets.

**Batch Size**— The test batch or lot must be manufactured under production conditions and must be of a size that is at least 10% of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.

**Potency**— The assayed potency of the reference product should not differ from that of the test product by more than 5%.

#### Types of Studies Required—

1. A single-dose, randomized, two-period, two-treatment, two-sequence crossover study under fasting conditions comparing equal doses (two 5-mg tablets, total dose 10-mg) of the test and reference products.
2. A single-dose, randomized, three-treatment, three-period, six-sequence crossover, limited food effects study comparing equal doses (two 5-mg tablets, total dose 10 mg) of the test and reference products when administered immediately following a high-fat breakfast.<sup>6</sup>

#### Recommended Protocol for Conducting a Single-Dose Bioequivalence Study under Fasting Conditions—

**Objective**— The objective is to compare the rate and extent of absorption of a generic formulation with that of the reference formulation when given as equal labeled doses.

**Design**— The study design is a single-dose, two-treatment, two-period, two-sequence crossover with a 2-week washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to each of the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

**Facilities**— The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

**Selection of Subjects**— The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 24 subjects be used in this study. Subjects should be healthy, preferably nonsmoking, volunteers aged 18 to 50 years and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of acceptable medical history, physical examination, and clinical laboratory test results. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. If smokers are included, they should be identified as such. Written, informed consent must be obtained from all study participants before they are accepted into the study.

**Procedure**— Following an overnight fast of at least 10 hours, subjects should be administered two 5-mg tablets (10 mg total dose) of the test or reference product with 240 mL of water.

**Restrictions**— Study volunteers should observe the following restrictions:

- a. Water may be taken, except for 1 hour before and after drug administration when no liquid is allowed other than that needed for drug dosing.
- b. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- c. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- d. Subjects should take no Rx medications, including oral contraceptives, beginning 2 weeks and no OTC medications beginning 1 week before drug administration and until after the study is completed.

**Blood Sampling**— Venous blood samples should be collected pre-dose (0 hours) and at 0.25, 0.5, 0.75, 1, 1.5, 2, 2.5, 3, 3.5, 4, 4.5, 5, 6, 8, 12, 24, 36, 48, 72, and 96 hours post-dose. Plasma or serum should be separated promptly and immediately frozen until assayed. Following a 2-week washout period, subjects should begin the second phase of the study.

**Subject Monitoring**— Blood pressure and pulse rate should be monitored hourly during the first 4 hours of the study. Subjects with a heart rate less than 45 bpm or greater than 110 bpm should have an electrocardiogram (lead II) performed and have their pulse monitored hourly. Subjects should report any unusual symptoms observed during the study. Subjects should be periodically questioned during each phase of the study for any unusual symptoms experienced after drug administration.

Analytical Methods— Selegiline and its three metabolites desmethylselegiline (DES), methamphetamine (MA), and amphetamine (A) should be assayed using a suitable method fully validated with respect to adequate sensitivity, specificity, linearity, recovery, accuracy, and precision (both within and between days). Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined. Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

Statistical Analysis of Pharmacokinetic Data— See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances. Pivotal statistical criteria should be applied to the three selegiline metabolites, desmethylselegiline (DES), methamphetamine (MA), and amphetamine (A). Results should also be reported for selegiline.

#### Limited Food Effects Study—

Objective— The objective is to compare the rate and extent of absorption of selegiline from a generic formulation with that from a reference formulation under nonfasting conditions and to compare the rate and extent of absorption of the drug from a generic formulation under fasting and nonfasting conditions when given as equal labeled doses.

Design— The study design is a single-dose, randomized three-treatment, three-period, six-sequence crossover with a 2-week washout period between Phase I and Phase II, and Phase II and Phase III. An equal number of subjects should be assigned to each of the six dosing sequences.

The limited food effects study should be performed in the same manner as directed under Recommended Protocol for Conducting a Single-Dose Bioequivalence Study under Fasting Conditions, with the following exceptions:

Procedure— An equal number of subjects should be assigned to each of the six dosing sequences possible in a three-treatment, three-period study design (minimum 18 subjects).

Each subject will receive the following treatments:

TREATMENT 1: Generic selegiline hydrochloride product, (two 5-mg tablets, total dose 10 mg) administered after a high-fat breakfast.

TREATMENT 2: Reference product (two 5-mg Eldepryl® tablets, total dose 10 mg) administered after a high-fat breakfast.

TREATMENT 3: Generic selegiline hydrochloride product (two 5-mg tablets, total dose 10 mg) administered under fasting conditions.

Following a 10-hour fast, the subjects receiving the treatments under nonfasting conditions should be served the indicated high-fat breakfast. The subjects should have 30 minutes to finish the entire breakfast, then should immediately receive Treatment 1 or Treatment 2, taken with 240 mL of water. Subjects receiving the treatment under fasting conditions should receive Treatment 3, taken with 240 mL of water only. The same lots of the test and reference products should be used as in the fasting and nonfasting studies. No food should be allowed for at least 4 hours post-dose, with water allowed after the first hour. Subjects should be served scheduled standardized meals throughout the study, and the same meals should be served during all phases of the study.

Statistical Analysis— In general, a comparable food effect will be assumed if the AUC<sub>0-t</sub>, AUC<sub>0-∞</sub>, and C<sub>max</sub> mean values for the test product administered under nonfasting conditions are within 20% of the respective mean values obtained for the reference product administered under nonfasting conditions.

Clinical Report, Side Effects, and Adverse Reactions— Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions and side effects to the study formulations should be reported.

Retention of Samples— The laboratory conducting the bioequivalence testing should retain appropriately identified reserve samples of both the test and reference products used to perform the in vivo bioequivalence study for approval of the application. Each reserve sample should consist of at least 200 dosage units or 5 times the amount needed for complete release testing and should be retained for a minimum of 5 years following approval of the application. For more information on retention of bioequivalence samples, refer to 21 CFR 320.63.

#### in vitro testing requirements

Dissolution Testing— Conduct dissolution testing on 12 dosage units of the test and reference products employing the biostudy lots. The current official USP dissolution method should be followed, and should be referenced by the sponsor. The following times should be used to determine the dissolution profile:

Times: 5, 10, 20, and 30 minutes.

The percentage of label claim dissolved at each specified testing interval should be reported for each individual dosage unit. The mean percentage dissolved, the range (highest, lowest) of dissolution, and the coefficient of variation (relative standard deviation) should be reported.

Content Uniformity Test (905)— Content uniformity testing on the test and reference product lots should be performed as described in USP.

#### Tolmetin Sodium Capsules and Tablets—In Vivo Bioequivalence and In Vitro Dissolution Testing<sup>4</sup>

Clinical Pharmacology/Usage— Tolmetin sodium is a nonsteroidal anti-inflammatory agent freely soluble in water. Its mode of action is unknown. The drug is indicated for the relief of signs and symptoms of rheumatoid arthritis and osteoarthritis, both in the treatment of acute episodes and the long-term management of the chronic disease. In adults with rheumatoid arthritis, the recommended starting dose is 400 mg three times daily (1200 mg daily), preferably including a dose on arising and a dose at bedtime.

Pharmacokinetics— The drug is rapidly and almost completely absorbed following oral dosing, with peak plasma levels reached in 30 to 60 minutes. Tolmetin displays a biphasic elimination from plasma consisting of a rapid phase (T<sub>1/2</sub>, about 1 to 2 hours) followed by a slower phase (T<sub>1/2</sub>, about 5 hours). Essentially all of the dose is recovered in the urine within 24 hours either as an active metabolite or as conjugates of tolmetin. Peak plasma levels of about 40 to 50 µg per mL were obtained with a 400-mg oral dose. When taken immediately after a meal, peak plasma drug levels decreased by 50%, while total bioavailability was decreased by 16%. Administration with milk alone had no effect on peak plasma drug concentrations but decreased the total tolmetin bioavailability by 16%.

#### in vivo bioequivalence studies<sup>5</sup>

##### Product Information—

FDA Designated Reference Product: Tolectin® (McNeil Pharmaceutical) 400-mg capsules and 600-mg tablets.

Batch Size— The test batch or lot must be manufactured under production conditions and must be of a size at least 10% that of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.

Potency— The assayed potency of the reference product should not differ from that of the test product by more than 5%.

#### Types of Studies Required—

1. A single-dose, randomized, two-period, two-treatment, two-sequence crossover study under fasting conditions comparing equal doses of the test and reference products.
2. A single-dose, randomized, three-treatment, three-period, six-sequence crossover, limited food effects study comparing equal doses of the test and reference products when administered immediately following a standard high-fat breakfast.<sup>6</sup>

#### Recommended Protocols for Conducting a Single-Dose, Fasted Bioequivalence Study—

Objective— The objective is to compare the rate and extent of absorption of tolmetin sodium of a generic formulation with that of a reference formulation when given as equal labeled doses.

Design— The study design is a single-dose, two-treatment, two-period, two-sequence crossover with a 1-week washout period between Phase I and Phase II dosing. An equal number of subjects should be randomly assigned to each of the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

Facilities— The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

**Selection of Subjects**—The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 24 subjects be used in this study. Subjects should be healthy, preferably nonsmoking, volunteers aged 18 to 55 and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be selected on the basis of acceptable medical history, physical examination, and clinical laboratory test results. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. If smokers are included, they should be identified as such. Written, informed consent must be obtained from all study participants before they are accepted into the study.

**Procedure**—Following an overnight fast of at least 10 hours, subjects should be administered a single 400-mg dose (for capsules) or a single 600-mg dose (for tablets) of the test or reference product with 240 mL of water.

**Restrictions**—Study volunteers should observe the following restrictions:

- a. Water may be taken except for 1 hour before and after drug administration when no liquid is allowed other than that needed for drug dosing.
- b. Subjects should fast for at least 4 hours after administration of the test or reference treatment. All meals should be standardized during the study, and the same meals should be served during both phases of the study.
- c. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- d. Subjects should take no Rx medications, including oral contraceptives, beginning 2 weeks and no OTC medications beginning 1 week before drug administration and until after the study is completed.

**Blood Sampling**—Venous blood samples should be collected pre-dose (0 hours) and at 0.17, 0.33, 0.50, 0.75, 1, 1.5, 2, 2.5, 3, 4, 6, 8, 10, 12, 16, and 20 hours post-dose. Plasma should be separated promptly and immediately frozen until assayed. Following a minimum 1-week washout period, subjects should begin the second phase of the study.

**Subject Monitoring**—Blood pressure and pulse rate should be monitored hourly during the first 4 hours of the study. Subjects with a heart rate less than 45 bpm or greater than 110 bpm should have an electrocardiogram (lead II) performed and have their pulse monitored hourly. Subjects should report any unusual symptoms observed during the study. Subjects should be periodically questioned during each phase of the study for any unusual symptoms experienced after drug administration.

**Analytical Methods**—Tolmetin should be assayed using a suitable method fully validated with respect to adequate sensitivity, specificity, linearity, recovery, accuracy, and precision (both within and between days). Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined.

Chromatograms of the analysis of the unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities. The sponsor should justify the rejection of any analytical data and provide a rationale for selection of the reported values.

**Statistical Analysis of Pharmacokinetic Data**—See Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design under General Guidances.

**Limited Food Effects Study**—

**Objective**—The objective is to compare the rate and extent of absorption of tolmetin sodium from a generic formulation with that from a reference formulation under nonfasting conditions and to compare the rate and extent of absorption of the drug from a generic formulation under fasting and nonfasting conditions when given as equal labeled doses.

**Design**—The study design is a single-dose, three-treatment, three-period, six-sequence crossover with a 1-week washout period between Phase I and Phase II, and Phase II and Phase III.

The limited food effects study (minimum 12 subjects) should be performed in the same manner as the single-dose study under fasting conditions, with the following exceptions:

**Procedure**—An equal number of subjects should be assigned to each of the 6 dosing sequences possible in a three-treatment, three-period study design. Each subject will receive the following treatments:

TREATMENT 1: Generic product, a 400-mg capsule or 600-mg tablet administered after a standard high-fat breakfast.

TREATMENT 2: Reference product, a 400-mg Tolectin® capsule or 600-mg Tolectin® tablet administered after a standard high-fat breakfast.

TREATMENT 3: Generic product, a 400-mg capsule or 600-mg tablet administered under fasting conditions.

Following a 10-hour fast, the subjects receiving treatments under fed conditions should be served a standard high-fat breakfast. The subjects should have 30 minutes to finish the entire breakfast and then should immediately receive Treatment 1 or Treatment 2, taken with 240 mL of water. Subjects receiving the treatment under fasting conditions should receive Treatment 3, taken with 240 mL of water only. The same lots of the test and reference products should be used in the fasted and fed studies. No food should be allowed for at least 4 hours post-dose with water allowed after the first hour. Subjects should be served scheduled standardized meals throughout the study, and the same meals should be served during all phases of the study.

**Statistical Analysis**—In general, a comparable food effect will be assumed if the AUC<sub>0-t</sub>, AUC<sub>0-∞</sub>, and C<sub>max</sub> mean values for the test product administered under fed conditions are within 20% of the respective mean values obtained for the reference product administered under fed conditions.

**Clinical Report, Side Effects, and Adverse Reactions**—Subject medical histories, physical examinations and laboratory reports, and all incidents of possible adverse reactions and side effects to the study formulations should be reported.

**Retention of Samples**—The laboratory conducting the bioequivalence testing should retain appropriately identified reserve samples of both the test and reference products used to perform the *in vivo* bioequivalence studies for approval of the application. Each reserve sample should consist of at least 200 dosage units or 5 times the amount needed for complete release testing, whichever is greater, and should be retained for a minimum of 5 years following approval of the application. For more information on retention of bioequivalence samples refer to 21 CFR 320.63.

**in vitro testing requirements**

**Dissolution Testing**—Conduct dissolution testing on 12 dosage units of the test product and the reference product, employing the biostudy lots. The current official USP dissolution method (see [Dissolution](#) (711)) should be followed and should be referenced by the sponsor. The following times should be used to determine the dissolution profile: Times: 10, 20, 30, and 45 minutes.

The percentage of label claim dissolved at each specified testing interval should be reported for each individual dosage unit. The mean percentage dissolved, the range (highest, lowest) of dissolution, and the coefficient of variation (relative standard deviation) should be reported.

**Content Uniformity Test**—Content uniformity testing on the test and reference product lots should be performed as described in USP.

**waiver requirements**

Waiver of *in vivo* bioequivalence study requirements for the 200-mg strength of the generic tablet product may be granted pursuant to 21 CFR 320.22(d)(2) provided the following conditions are met:

1. The 200-mg tablet is proportionally similar in both active and inactive ingredients to the firm's 600-mg tablet which has been demonstrated to be bioequivalent to the reference product *in vivo*.
2. The 200-mg tablet of the generic product meets dissolution test requirements.

**Auxiliary Information**—Please [check for your question in the FAQs](#) before contacting USP.

## GENERAL GUIDANCES

Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design<sup>2</sup>

## introduction

The FDA Division of Bioequivalence in the Office of Generic Drugs usually evaluates bioequivalence by comparing the in vivo rate and extent of drug absorption of a test and reference formulation in healthy subjects. In a standard in vivo bioequivalence study design, study participants receive test and reference products on separate occasions, in either single or multiple doses, with random assignment to the two possible sequences of product administration. Samples of an accessible biologic fluid such as blood or urine are analyzed for drug and metabolite concentrations, and pharmacokinetic parameters (AUC, Cmax and Tmax) are obtained from the resulting concentration-time curves. These pharmacokinetic parameters are then analyzed statistically to determine if the test and reference products yield comparable values.

Standard statistical methodology based on the null hypothesis is not appropriate to assess bioequivalence. The Division of Bioequivalence has therefore employed a testing procedure termed the two one-sided tests procedure to determine whether average values for pharmacokinetic parameters measured after administration of the test and reference products are comparable. This procedure involves the calculation of a confidence interval for the ratio (or difference) between the test and reference product pharmacokinetic variable averages. The limits of the observed confidence interval must fall within a predetermined range for the ratio (or difference) of the product averages. The determination of the confidence interval range and the statistical level of significance are judgments made by the Division of Bioequivalence.

This guidance provides information about general pharmacokinetic and statistical analyses of bioequivalence data to be conducted by sponsors of abbreviated new drug and antibiotic applications and addresses three specific aspects of the statistical analysis as follows:

1. Logarithmic transformation of pharmacokinetic data
2. Sequence effect
3. Outlier consideration.

This guidance became effective July 1, 1992. Any investigations initiated after this date should generally conform to the recommendations of the guidance. Sponsors following a different approach are encouraged to discuss the matter in advance with the FDA to prevent the expenditure of money and effort on preparing a submission that may later be determined to be unacceptable.

## general methodology

## Pharmacokinetic Analysis—

Single-Dose Studies— At a minimum, the following pharmacokinetic parameters for the substances of interest should be measured in a single-dose bioequivalence study:

- a. Area under the plasma/blood concentration-time curve from time zero to time t (AUC<sub>0-t</sub>), calculated by the trapezoidal rule, where t is the last measurable time point.
- b. Area under the plasma/blood concentration-time curve from time zero to time infinity (AUC<sub>0-∞</sub>), where AUC<sub>0-∞</sub> = AUC<sub>0-t</sub> + Ct /  $\lambda_Z$ , Ct is the last measurable drug concentration, and  $\lambda_Z$  is the terminal elimination rate constant calculated according to an appropriate method. The terminal or elimination half-life of the drug (t<sub>1/2</sub>) should also be reported.
- c. Peak drug concentration (Cmax) and the time to peak drug concentration (Tmax), obtained directly from the data without interpolation.

Multiple-Dose Studies— At a minimum, the following pharmacokinetic parameters for the substances of interest should be measured in a multiple-dose bioequivalence study:

- a. Area under the plasma/blood concentration-time curve from time zero to time  $\tau$  over a dosing interval at steady state ( $AUC_{0-\tau}$ ), where  $\tau$  is the dosing interval.
- b. Peak drug concentration ( $C_{max}$ ) and the time to peak drug concentration ( $T_{max}$ ), obtained directly from the data without interpolation, after the last dose is administered.
- c. Drug concentrations at the end of each dosing interval during steady state ( $C_{min}$ ).
- d. Average drug concentration at steady state ( $C_{av}$ ), where  $C_{av} = AUC_{0-\tau}/\tau$ .
- e. Degree of fluctuation (DF) at steady state, where  $DF = 100\% \times (C_{max} - C_{min})/C_{av}$ .

Evidence of attainment of steady state for the test and reference products should be submitted in the bioequivalence study report.

Statistical Analysis— Parametric (normal-theory) general linear model procedures are recommended for the analysis of pharmacokinetic data derived from in vivo bioequivalence studies. An analysis of variance (ANOVA) should be performed on the pharmacokinetic parameters AUC and  $C_{max}$  using appropriate statistical programs and models. For example, for a conventional two-treatment, two-period, two-sequence ( $2 \times 2$ ) randomized crossover study design, the statistical model often includes factors accounting for the following sources of variation:

1. Sequence (sometimes called Group or Order)
2. Subjects, nested in sequences
3. Period (or Phase)
4. Treatment (sometimes called Drug or Formulation).

The sequence effect should be tested using the [subject (sequence)] mean square from the ANOVA as an error term. All other main effects should be tested against the residual error (error mean square) from the ANOVA. The least square means (LSMEANS) statement should be used to calculate least square means for treatments. Estimates should be obtained for the adjusted differences between treatment means and the standard error associated with these differences.

The two one-sided hypotheses at the  $\alpha = 0.05$  level of significance should be tested for AUC and  $C_{max}$  by constructing the 90% confidence interval for the ratio between the test and reference averages.

logarithmic transformation of pharmacokinetic data

Statistical Assumptions— The assumptions underlying the ANOVA are:

1. Randomization of samples
2. Homogeneity of variances
3. Additivity (linearity) of the statistical model
4. Independence and normality of residuals.

In bioequivalence studies, these assumptions can be interpreted as follows:

1. The subjects chosen for the study should be randomly assigned to the sequences of the study.
2. The variances associated with the two treatments, as well as between the sequence groups, should be equal or at least comparable.
3. The main effects of the statistical model, such as subject, sequence, period, and treatment effect for a standard  $2 \times 2$  crossover study, should be additive. There should be no interactions between these effects.
4. The residuals of the model should be independently and normally distributed. In other words, data from bioequivalence studies should have a normal distribution.

If these assumptions are not met, additional steps should be taken prior to the ANOVA including data transformation to improve the fit of the assumptions or use of a nonparametric statistical test in place of ANOVA. However, the normality and constant variance assumptions in the ANOVA model are known to be relatively robust [i.e., a small or moderate departure from each (or both) of these assumptions will not have a significant effect on the final result].

Rationale for Log Transformation— It is acceptable to use logarithms to the base 10 or natural logarithms ( $\ln$ ). The report must state unambiguously which logarithms were used, and the use must be consistent throughout.

Clinical Rationale— The primary comparison of interest in a bioequivalence study is the ratio of average parameter data from the test and reference formulations rather than the difference between them. Using log transformation, the general linear statistical model employed in the analysis of bioequivalence data allows inferences about the difference between the two means on the log scale, which can then be retransformed into inferences about the ratio of the two averages (means or medians) on the original scale. Log transformation thus achieves the general comparison based on the ratio rather than the difference.

Pharmacokinetic Rationale— Westlake observed that a multiplicative model is postulated for pharmacokinetic parameters in bioavailability/bioequivalence studies, i.e., AUC and  $C_{max}$  (but not  $T_{max}$ ). Assuming that elimination of the drug is first order and only occurs from the central compartment, the following equation holds after an extravascular route of administration:

$$\begin{aligned} AUC_{0-\infty} &= FD/CL \\ &= FD/(V\text{Ke}) \end{aligned}$$

where  $F$  is the fraction absorbed,  $D$  is the administered dose, and  $FD$  is the amount of drug absorbed.  $CL$  is the clearance of a given subject, which is the product of the apparent volume of distribution ( $V$ ) and the elimination rate constant ( $\text{Ke}$ ).<sup>3</sup>

The use of AUC as a measure of the amount of drug absorbed thus involves a multiplicative term ( $CL$ ), which might be regarded as a function of the subject. For this reason, Westlake contends that the subject effect is not additive if the data is analyzed on the original scale of measurement.

Logarithmic transformation of the AUC data will bring the  $CL(V\text{Ke})$  term into the equation in an additive fashion:

$$\ln AUC_{0-\infty} = \ln F + \ln D - \ln V - \ln \text{Ke}$$

Similar arguments were given for  $C_{max}$ . The following equation applies for a drug exhibiting one compartmental characteristic:

$$C_{max} = (FD/V) \times e^{(-\text{Ke} \times T_{max})}$$

where again  $F$ ,  $D$ , and  $V$  are introduced into the model in a multiplicative manner. However, after logarithmic transformation the equation becomes

$$\ln C_{max} = \ln F + \ln D - \ln V - \text{Ke}T_{max}$$

Log transformation of the Cmax data also results in the additive treatment of the V term.

**Statistical Rationale**— Logarithmic transformation of the data from bioequivalence studies can be used to circumvent the use of estimates of the reference product average for computation of the confidence interval for the ratio of product averages. This is an advantage for the cases where a least square estimate for the reference product mean is not well defined. Standard parametric methods are ill-suited to making inferences about the ratio of two averages, though some valid methods do exist. Log transformation changes the problem to one of making inferences about the difference (on the log scale) of two averages, for which the standard methods are well suited.

Many biological data correspond more closely to a log-normal distribution than to a normal distribution. The plasma concentration data, including the derived parameters AUC and Cmax, tend to be skewed, and their variances tend to increase with the means. Log transformation is likely to remedy this situation and make the variances independent of the mean. In addition, frequency distributions skewed to the left (with a long tail to the right) are often made more symmetrical by log transformation.

This argument is actually less persuasive than the argument based on the additivity of the statistical model because it is based largely on the between-subject distribution of AUC and Cmax values. For crossover studies, it is largely the within-subject distribution of values that determines the validity and efficiency of the standard parametric methods of analysis. Despite the arguments regarding the effect of log transformation on normality of bioequivalence data, it is recognized that the limited sample size (20–30 subjects) in a bioequivalence study precludes a reliable determination of the underlying normal distribution of the data set either with or without log transformation.

**General Procedures**— Pharmacokinetic parameters AUC and Cmax should be log transformed. Firms are not encouraged to test for normality of data distribution after log transformation, nor should they employ normality of data distribution as a justification for carrying out the statistical analysis on the original scale. Robustness of a balanced study to non-normality of the data plus use of log transformation will be adequate in most cases.

If a firm believes that the data of a particular bioequivalence study should be statistically analyzed on the untransformed basis rather than the log scale, justification based upon a sound scientific rationale, as well as the statistical methods to be used, ought to be submitted to and reviewed by the FDA Division of Bioequivalence or a comparable regulatory authority.

**Presentation of Data**— The drug concentration in biological fluid at each sampling time point should be furnished untransformed for all the subjects who participated in the study. The derived pharmacokinetic parameters should also be furnished untransformed. The mean, the standard deviation, and the coefficient of variation for each variable should be computed and tabulated in the final report.

To facilitate bioequivalence comparisons, pharmacokinetic parameters for each individual should be displayed in parallel for the formulations tested. In particular, for AUC and Cmax, the difference ( $T - R$ ), ratio ( $T/R$ ), and log of ratio ( $\log T/R$  or  $\ln T/R$ ) between the test and reference values should be tabulated side by side for all the subjects. For each subject, the summary tables should indicate in which sequence (test, reference or reference, test) the subject received the product. Histograms showing the frequency distribution of the difference and  $\ln$  ratio (or log ratio) for the major pharmacokinetic parameters (AUC and Cmax) are useful in the submission.

In addition to the arithmetic mean for the test and reference products, the geometric means (antilog of the means of the logs), means of the logs, and standard deviations of the logs should be calculated for AUC and Cmax. All means, including arithmetic mean, geometric mean, and means of the logs, as well as standard deviations and coefficients of variation, are to be included in the report.

**Equivalence Criteria**— For a broad range of drugs, the FDA Division of Bioequivalence used a range of 80% to 120% for the ratio of the product averages as the standard equivalence criterion when the study data are analyzed on the untransformed basis. This corresponds to a range of  $\pm 20\%$  for the relative difference between the product averages.

When log-transformed data are used in the analysis of AUC and Cmax, using a range of 80% to 125% for the ratio of averages has an advantage over the 80% to 120% criterion in that for the analysis of log-transformed data, the probability of concluding equivalence is at a maximum if the ratio of averages is in fact 1.0 (i.e., exact equality). For the analysis of log-transformed data with a criterion of 80% to 120%, the maximum probability of concluding equivalence occurs when the ratio of product averages equals approximately 0.98. Thus, an equivalence criterion of 80% to 125% is used for the ratio of the product averages.

The 90% confidence interval for the difference in the means of the log-transformed data should be calculated using methods appropriate to the experimental design. The antilogs of the confidence limits constitute the 90% confidence interval for the ratio of the test and reference product averages.

#### sequence effect

A major limitation of a conventional two-treatment, two-period, two-sequence crossover design is the confounding between (i) a true sequence or group effect, (ii) unequal residual or carryover effects, and (iii) treatment-by-period interactions. A true sequence effect (i.e., a difference between the average response for sequence group one and sequence group two) would not bias the determination of bioequivalence. Unequal residual effects, however, would bias this estimate. A treatment-by-period interaction based on an underlying physical basis (i.e., if there were actually something about the periods that caused the difference between the product averages to differ from one period to another), would lead to difficulties in interpreting the estimate of the ratio (difference) in the pharmacokinetic parameters between the test and reference formulations.

Even if there were no true sequence effect, no unequal residual effects, and no treatment-by-period statistical interaction, approximately 10 out of every 100 two-treatment crossover studies would be likely to show an apparent sequence effect, if the testing is carried out at the 10% level of significance.

If the ANOVA test for the presence of a sequence effect results in statistical significance, the actual cause cannot be determined from the data alone. In some cases, plausible causes might be evaluated by examining demographic or physiological subject data, but this examination is seldom conclusive.

On the basis of these considerations, an in vivo two-treatment, two-period, two-sequence crossover bioequivalence study showing a statistically significant sequence effect may be acceptable provided:

1. It is a single-dose study;
2. It includes only healthy, normal subjects;
3. The drug is not an endogenous entity;
4. More than adequate washout period has been allowed between the two phases of the study, and in the second phase, the predose biological matrix samples do not exhibit any detectable drug level in all subjects; and
5. The study meets all scientific and statistical criteria such as:
  - a. It is based upon an acceptable study protocol;
  - b. It contains an acceptable validated assay methodology;
  - c. The study data are acceptable;
  - d. Appropriate statistical analyses of the data are performed; and
  - e. Acceptable confidence intervals for the pharmacokinetic parameters are achieved.

Under all other circumstances, the sponsor may be asked to conduct another study. After regulatory review, multiple-dose studies or studies in patients demonstrating a statistically significant sequence effect may be acceptable provided they meet all other criteria listed above.

#### outlier consideration

Outliers are defined in bioequivalence studies as subjects having discordant values of one or more pharmacokinetic parameters when compared with other values in a study. Because bioequivalence studies are usually carried out as crossover studies, the most important type of outlier is where one or a few subjects differ notably from the rest of the subjects for the test product response versus the reference product response (e.g., test minus reference difference, test/reference ratio, or the  $\log$  of the test/reference ratio).

The existence of an outlier could be indicative of the following problems with interchangeability of two formulations:

**Product Failure**— A subject obtained an unusually high or low response to one or the other of the products because of a problem with the specific dosage unit(s) administered. Examples include a modified- or extended-release dosage form exhibiting dose dumping or a dosage unit whose coating inhibited dissolution.

Subpopulation— A subject may be representative of a type of subject, present in the general population in low numbers, for whom the relative bioavailability of the two products is markedly different than it is for the majority of the population, and for whom the two products are not bioequivalent, even though they might be bioequivalent in the majority of the population.

In the case of product failure, it may make a difference whether the unusual response is observed on the test product or the reference product. In the case of a subpopulation, however, even if the unusual response is observed on the reference product, there may still be concern for lack of interchangeability of the two products.

Statistical tests exist for outlier identification. For detection of a single outlier, one important test is based on the absolute value of the "Studentized Residual." Out of all the data in the study, the test focuses on the most extreme. Approximate critical values for this test have been published by Lund.<sup>9</sup> In principle, however, outliers cannot be dropped from the analysis of the data solely on the basis of a statistical test. When one or more outliers are identified, one should provide scientific evidence or explanations to justify the exclusion of the subject data from statistical analysis.

#### Oral Extended-Release Dosage Forms<sup>4</sup>

This guidance describes *in vivo* bioequivalence studies and *in vitro* drug release testing recommended to applicants intending to submit Abbreviated New Drug Applications (ANDAs) for extended-release products administered orally.

##### nomenclature

Modified-Release Dosage Forms— A modified-release dosage form is one for which the drug release characteristics of time course and/or location are chosen to accomplish therapeutic or convenience objectives not offered by conventional dosage forms such as solutions, ointments, or promptly dissolving dosage forms. Delayed-release and extended-release dosage forms are two types of modified-release dosage forms. This guidance does not consider bioequivalence studies for delayed-release formulations.

Delayed-Release Dosage Forms— A delayed-release dosage form is one that releases a drug(s) at a time other than promptly after administration.

Extended-Release Dosage Forms— An extended-release dosage form is one that allows at least a twofold reduction in dosing frequency or significant increase in patient compliance or therapeutic performance as compared to that presented as a conventional dosage form (e.g., as a solution or a prompt drug-releasing, conventional solid dosage form).

The terms controlled release, prolonged action, and sustained release are used synonymously with extended release. This document uses the term extended release to describe a formulation that does not release active drug substance immediately after oral dosing and that also allows a reduction in dosage frequency. This nomenclature accords generally with the USP definition of extended release but does not specify an impact on dosing frequency. The terms controlled release and extended release are considered interchangeable in this guidance.

##### regulatory background and general requirements

The Drug Price Competition and Patent Term Restoration Act amendments of 1984 to the Food, Drug, and Cosmetic Act gave the Food and Drug Administration statutory authority to accept and approve for marketing ANDAs for generic substitutes of innovator products, including those approved after 1962. To gain approval, ANDAs for a generic extended-release formulation must demonstrate, among other things, that the formulation is both pharmaceutically equivalent and bioequivalent to the innovator extended-release product, which is also termed the reference listed product as identified in FDA's Approved Drug Products with Therapeutic Equivalence Rating, "The Orange Book" (USP DI, Volume III).

Pharmaceutical Equivalence— To be pharmaceutically equivalent, the generic and innovator formulations must (1) contain the same active ingredient; (2) contain the same strength of the active ingredient in the same dosage form; (3) be intended for the same route of administration, and (4) generally be labeled for the same conditions of use. The FDA does not require that the generic and reference listed extended-release products contain the same excipients or that the mechanism by which the active drug substance is released from the formulation be the same.

Bioequivalence Studies— Current regulations require that bioequivalence be demonstrated between a generic extended-release formulation and the reference listed product. The reference listed product is generally an extended-release product subject to an approved full New Drug Application (NDA). For approval, documentation of bioequivalence must be established through performance of a series of *in vivo* bioequivalence studies that are defined under the section *In Vivo Bioequivalence Studies for Approval*. Approval of an ANDA will rely on data derived from evaluation of a biobatch, which is to be manufactured in accordance with the Office of Generic Drugs Procedure and Policy Guide 22-90.

Quality control of the manufacture of an extended-release formulation after approval may be assessed, in part, through performance of *in vitro* dissolution tests. Preapproval submission of these data is required. Recommendations for the conditions under which this test may be performed are described under the section *In Vitro Dissolution for Quality Control Preapproval*. This section also describes how specifications for this test are developed by the applicant and approved by the Division of Bioequivalence. These data are required in the application for approval.

##### *in vivo* bioequivalence studies for approval

*In vivo* bioequivalence studies recommended for approval for extended-release generic formulations are designed to document the following:

- The drug product meets the extended-release claim made for it.
- The drug product does not release the active drug substance at too rapid a rate (dose dumping).
- Performance is equivalent between the generic and the reference listed product following single doses and dosing to steady state.
- The influence of food on the *vivo* performance is comparable for the generic formulation relative to the innovator formulation.

The above objectives are generally met by three *in vivo* studies: (1) a single-dose, randomized, two-period, two-treatment, two-sequence crossover study under fasting conditions, comparing equal doses of the test and reference products; (2) a single-dose, randomized, three-treatment, three-period, six-sequence, crossover, limited food effects study, comparing equal doses of the test product administered under fasting conditions with those of the test and reference products administered immediately after a standard high-fat breakfast<sup>8</sup>; and (3) a multiple-dose, steady state, randomized, two-treatment, two-period, two-sequence crossover study under fasting conditions comparing equal doses of the test and reference formulations. [note—For safety reasons, this study may be performed in the nonfasting state. Applicants are encouraged to submit a study protocol describing the safety considerations requiring deviation from the fasting state to the Division of Bioequivalence for review prior to execution of the study.]

These studies are described in detail below. Under certain circumstances, the Division of Bioequivalence in the Office of Generic Drugs may require additional single-dose or multiple-dose steady state studies. The following general information relative to the three *in vivo* studies is provided:

- FDA-designated reference product is identified by the symbol "+" in The Orange Book.
- The assayed potency of the test product should not differ from that of the reference product by more than 5%.
- The clinical laboratory conducting any *in vivo* study should retain an appropriately identified reserve sample of the test and reference products for a period of 5 years. Each reserve sample should consist of at least 200 dosage units. For more information on retention of bioequivalence samples, refer to 21 CFR 320.63.
- A single-dose two-way crossover study under fasting conditions is required for each strength of a generic extended-release tablet formulation with multiple strengths. The multiple-dose steady state study and the fasting/nonfasting single-dose three-way crossover study are to be conducted with the highest strength only.

For an extended-release bead type capsule formulation to be marketed in multiple strengths, a single-dose bioequivalence study under fasting conditions is required only on the highest strength, provided that the compositions of the lower strengths are proportional to that of the highest strength, and the capsules contain identical beads or pellets. Single-dose *in vivo* bioequivalence studies may be waived for the lower strengths on the basis of acceptable drug release profiles. Multiple-dose steady state and single-dose fasting/nonfasting studies are to be conducted on the highest strength of the capsule formulation.

Batch Size— The test batch or lot must be manufactured under production conditions and must be of a size that is at least 10% of the largest lot planned for full production or a minimum of 100,000 units, whichever is larger.

##### *single-dose* fasting two-way crossover bioequivalence study

Objective— The objective is to compare the rate and extent of absorption of a generic extended-release product with that of the reference-listed product when administered in equal labeled doses.

Design— The study design is a single-dose, two-treatment, two-period, two-sequence crossover with an adequate washout period (usually equal to at least 10 elimination half-lives of

the drug) between the two phases of the study. An equal number of subjects should be randomly assigned to the two possible dosing sequences. Before the study begins, the proposed protocol should be approved by an institutional review board.

**Facilities**— The clinical facilities and analytical laboratory used for the study should be identified along with the names, titles, and curriculum vitae of the medical and scientific or analytical directors.

**Selection of Subjects**— The sponsor should enroll a number of subjects sufficient to ensure statistical validity of the study. It is recommended that a minimum of 24 subjects be used in this study. More subjects may be required for a drug that exhibits high intra-subject variability in metrics of rate and extent of absorption. Subjects should be healthy, preferably nonsmoking, volunteers 18 to 50 years of age, and within 10% of ideal body weight for height and build, although within 15% of ideal body weight is acceptable (Metropolitan Life Insurance Company Statistical Bulletin, 1983). Subjects should be accepted on the basis of acceptable medical history, physical examination, and clinical laboratory tests. Female subjects must be given a pregnancy test prior to beginning the study. Subjects with any current or past medical condition that might significantly affect their pharmacokinetic or pharmacodynamic response to the administered drug should be excluded from the study. If smokers are included, they should be identified as such. Written, informed consent must be obtained from all subjects before they are accepted into the study.

**Procedure**— Following an overnight fast of at least 10 hours, subjects should be administered a single dose of the test or reference product with 240 mL of water. They should continue fasting for 4 hours after administration of the test or reference treatment.

**Restrictions**— Study volunteers should observe the following restrictions:

- a. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- b. Subjects should take no Rx medications, including oral contraceptives, beginning two weeks prior to and no OTC medications beginning one week prior to initiation of the study and until after the study is completed.
- c. Water may be taken except for 1 hour before and after administration, when no liquid is allowed other than that needed for drug dosing.
- d. All meals during the study should be standardized, and the same meals should be served during both phases of the study.

**Blood Sampling**— In addition to the pre-dose (0 hour) sample, venous blood samples should be collected post-dose so that there are at least four sampling time points on the ascending part and six or more on the descending part of the concentration-time curve. The biological matrix (plasma, serum, or whole blood) should be immediately frozen after collection and, as appropriate, centrifugation, and kept frozen until assayed.

**Subject Monitoring**— Blood pressure and pulse rate should be monitored hourly during the first 4 hours of the study. Subjects with a heart rate less than 45 bpm or greater than 110 bpm should have an electrocardiogram (lead II) performed and have their pulse monitored hourly. Subjects should report any unusual symptoms observed during the study. Subjects should be periodically questioned during each phase of the study for any unusual symptoms experienced after drug administration.

**Analysis of Blood Samples**— The active ingredient should be assayed using a suitable analytical method validated with regard to specificity, accuracy, precision (both within and between days), limit of quantitation, linearity, and recovery. Stability of the samples under frozen conditions, at room temperature, and during freeze-thaw cycles, if appropriate, should be determined. If the analytical method is a chromatographic method, chromatograms of unknown samples, including all associated standard curve and quality control chromatograms, should be available for regulatory authorities.

**Pharmacokinetic Analysis of Data**— Calculation of area under the plasma concentration-time curve to the last quantifiable concentration (AUC<sub>0-t</sub>) and to infinity (AUC<sub>0-∞</sub>), C<sub>max</sub>, and T<sub>max</sub> should be performed according to standard techniques.

**Statistical Analysis of Pharmacokinetic Data** (see Statistical Procedures for Bioequivalence Studies Using a Standard Two-treatment Crossover Design)— The log transformed AUC and C<sub>max</sub> data should be analyzed statistically using ANOVA. These two parameters for the test product should be shown to be within 80% to 125% of the reference product using the 90% confidence interval.

**Clinical Report, Side Effects, and Adverse Reactions**— Subject medical histories, physical examination and laboratory reports, and all incidents of possible adverse reactions to the study formulations should be reported.

multiple-dose steady state, two-way crossover bioequivalence study under fasting conditions

**Objective**— The objective is to compare the steady-state rate and extent of absorption of a generic extended-release formulation with that of the reference formulation when given as equal labeled doses.

**Design**— The study design is a multiple-dose, steady-state two-treatment, two-period, two-sequence crossover with an adequate washout period between the two phases of the study. An equal number of subjects should be randomly assigned to the two possible dosing sequences. Before beginning the study, the study protocol should be approved by an institutional review board.

**Facilities and Selection of Subjects**— See the appropriate section under Single-Dose Fasting Two-Way Crossover Bioequivalence Study.

**Procedure**— Extended-release products that are administered once a day should be dosed following an overnight fast of at least 10 hours; subjects should continue fasting for 4 hours post-dose. For extended-release products that are dosed every 12 hours (b.i.d.), the morning dose should be given following an overnight fast of about 10 hours, and subjects should continue fasting for 4 hours post-dose; the evening dose should be administered 12 hours after the morning dose and after a fast of at least 2 hours and subjects should continue fasting for 2 hours post-dose. Each dose should be administered with 240 mL of water.

**Restrictions**— Study volunteers should observe the following restrictions:

- a. No alcohol or xanthine-containing foods or beverages should be consumed for 48 hours prior to dosing and until after the last blood sample is collected.
- b. Subjects should take no Rx medications, including oral contraceptives, beginning two weeks prior to and no OTC medications beginning one week prior to initiation of the study and until after the study is completed.
- c. Water may be taken except for 1 hour before and after administration, when no liquid is allowed other than that needed for drug dosing.

**Blood Sampling**— At least three trough concentrations (C<sub>min</sub>) on three consecutive days should be determined to ascertain that the subjects are at steady state prior to measurement of rate and extent of absorption after a single-dose administration in a dosing interval at steady state. The three consecutive trough samples should be collected at the same time of the day and should be comparable. For extended-release drug products administered more often than every 24 hours, assessment of trough levels just prior to 2 consecutive doses is not recommended because a difference in the consecutive trough values may occur due to circadian rhythm irrespective of whether or not steady state has been attained. Adequate blood samples should be collected at appropriate times during a dosing interval at steady state to permit estimation of the total area under the concentration-time curve, peak concentration (C<sub>max</sub>), and time to peak concentration (T<sub>max</sub>).

**Subject Monitoring and Analysis of Blood Samples**— See under Single-Dose Fasting Two-Way Crossover Bioequivalence Study.

**Pharmacokinetic Analysis of Data**— The following pharmacokinetic data are to be reported for the evaluation of bioequivalence of the generic extended-release product with the reference listed product:

- a. Individual and mean blood drug concentration levels
- b. Individual and mean trough levels (C<sub>min</sub>)
- c. Individual and mean peak levels (C<sub>max</sub>)
- d. Calculation of individual and mean steady state AUC<sub>interdose</sub> is recommended (AUC<sub>interdose</sub> is AUC during a dosing interval at steady state)
- e. Individual and mean percent fluctuation [= 100 × (C<sub>max</sub> – C<sub>min</sub>)/C<sub>min</sub>]
- f. Individual and mean time to peak concentration (T<sub>max</sub>)

**Statistical Analysis of Pharmacokinetic Data**— The log transformed AUC and C<sub>max</sub> data should be analyzed statistically using ANOVA. These two parameters for the test product should be shown to be within 80% to 125% of the reference product using the 90% confidence interval. Fluctuation for the test product should be evaluated for comparability with that for the reference product. For further information on statistical analysis, see Statistical Procedures for Bioequivalence Studies Using a Standard Two-Treatment Crossover Design.

**Clinical Report, Side Effects, and Adverse Reactions**— See under Single-Dose Fasting Two-Way Crossover Bioequivalence Study.

## single-dose, three-way crossover fasting/nonfasting bioequivalence study

Objective— The objective is to compare the rate and extent of absorption of a generic formulation with that of the reference listed formulation under nonfasting conditions and to compare the rate and extent of absorption of the drug from a generic formulation under fasting and nonfasting conditions when given as equal labeled doses.

Design— The study design is a single-dose, three-treatment, three-period, six-sequence crossover with adequate washout period between the three phases of the study. An equal number of subjects should be randomly assigned to each dosing sequence. Before beginning the study, the study protocol should be approved by an institutional review board.

Facilities— See this section under Single-Dose Fasting Two-Way Crossover Bioequivalence Study.

Selection of Subjects— A minimum of 18 subjects should be enrolled in this study. For other information on selection of subjects, see Single-Dose Fasting Two-Way Crossover Bioequivalence Study.

Procedure— Each subject should receive the following three treatments:

treatment 1: Generic extended-release product administered after a high fat content breakfast

treatment 2: Innovator extended-release product (reference listed drug) administered after a high fat content breakfast.

treatment 3: Generic extended-release product administered after fasting.

Following an overnight fast of at least 10 hours, subjects receiving treatments under nonfasting conditions should be served a high-fat breakfast then immediately dosed with Treatment 1 or Treatment 2 with 240 mL of water. Subjects receiving Treatment 3 should be dosed at the same time as Treatments 1 and 2 with 240 mL of water only. No food should be allowed for at least 4 hours post-dose, with water allowed after the first hour. Subjects should be served scheduled standardized meals throughout the study, and the same meals should be served during all phases of the study.

Restrictions, Blood Sampling, Subject Monitoring, and Analysis of Blood Samples— See the appropriate section under Single-Dose Fasting Two-Way Crossover Bioequivalence Study.

Statistical Analysis of Pharmacokinetic Data— In general a comparable food effect will be assumed if the mean values of  $AUC_{0-t}$ ,  $AUC_{0-\infty}$ , and  $C_{max}$  for the generic product administered with food differ by no more than 20% from the respective mean values for the reference listed product administered with food in the study.

Clinical Report, Side Effects, and Adverse Reactions— See under Single-dose Fasting Two-way Crossover Bioequivalence Study.

in vitro drug release for quality control preapproval

Drug Release Testing (724)— Drug release testing should be conducted on 12 individual dosage units of the batches of the test and reference products used in the bioequivalence studies. The potential for pH dependence of drug release from an extended-release product is well recognized. Drug release profiles should therefore be generated in aqueous media at the following pH ranges: 1-1.5, 4-4.5, and 6.0-6.8. Early sampling times of 1, 2, and 4 hours should be included in the sampling schedule to provide assurance against premature release of the drug (dose dumping) from the formulation. Typical drug release conditions are shown below:

Apparatus 1 (for capsules): 100 rpm.

Apparatus 2 (for tablets): 50 and 75 rpm.

Temperature:  $37 \pm 0.5^\circ\text{C}$ .

Units Tested: 12.

Medium: 900 mL of aqueous media at various pH values.

Times: 1, 2, and 4 hours, and every 2 hours thereafter, until 80% of the drug is released.

Tolerances: to be established based on data generated.

Content Uniformity Test (905)— Content uniformity testing on the test and reference product lots should be performed as described in USP.

Specifications— Specifications for the drug release procedure to ensure quality control will be determined on a case-by-case basis. In general, further validation will be required to expand dissolution specifications beyond those established for the biobatch.

6 Each subject should consume a standardized, high-fat breakfast consisting of the following:

1 buttered English muffin

1 fried egg

1 slice of American cheese

1 slice of Canadian bacon

1 serving of hash brown potatoes

8 fluid oz. (240 mL) of whole milk

6 fluid oz. (180 mL) of orange juice

---

5 The sponsoring firm is advised that an Investigational New Drug (IND) application may be required if dosing levels exceed those recommended in the official labeling. See Policy and Procedure Guide 36-92, "Submission of an 'Investigational New Drug Application' to the FDA Office of Generic Drugs (OGD)" and 21 CFR 312.2 and 320.31(b)(1).

---

7 Glipizide (5 and 10 mg) and glyburide (1.25, 2.5, and 5 mg), the second generation sulfonylurea antidiabetic agents, are comparatively more potent than tolbutamide (250 and 500 mg) and tolazamide (100, 250, and 500 mg). Therefore, in a fasting bioequivalence study involving normal subjects, hypoglycemic events occur more frequently with glipizide and glyburide than with tolbutamide and tolazamide. In the case of glipizide, the hypoglycemic episodes in normal subjects participating in a fasting bioequivalence study were fewer when the glucose was given to subjects every 15 minutes than when it was given every 30 minutes. In a study with such a design, measurement of plasma glucose is not necessary because it will not reflect the pharmacodynamic endpoint. However, such design is preferable to the usual fasting study design to ensure the welfare of the subjects and to avoid excessive drop out rate.

---

8 Each subject should consume the following high-fat breakfast:

2 eggs fried in butter  
2 slices of toasted white bread spread with butter  
2 slices of bacon  
2 oz. of hash brown potatoes  
8 fluid oz. (240 mL) of whole milk

#### 1091 LABELING OF INACTIVE INGREDIENTS

This informational chapter provides guidelines for labeling of inactive ingredients present in dosage forms.

Within the past few years a number of trade associations representing pharmaceutical manufacturers have adopted voluntary guidelines for the disclosure and labeling of inactive ingredients. This is helpful to individuals who are sensitive to particular substances and who wish to identify the presence or confirm the absence of such substances in drug products.

Because of the actions of these associations, the labeling of therapeutically inactive ingredients currently is deemed to constitute good pharmaceutical practice.

Although the manufacturers represented by these associations produce most of the products sold in this country, not all manufacturers, repackagers, or labelers here or abroad are members of these associations. Further, there are some differences in association guidelines. The guidelines presented here are designed to help promote consistency in labeling.

In accordance with good pharmaceutical practice, all dosage forms [note—for requirements on parenteral and topical preparations, see the General Notices] should be labeled to state the identity of all added substances (therapeutically inactive ingredients) present therein, including colors, except that flavors and fragrances may be listed by the general term "flavor" or "fragrance." Such listing should be in alphabetical order by name and be distinguished from the identification statement of the active ingredient(s).

The name of an inactive ingredient should be taken from the current edition of one of the following reference works (in the following order of precedence): (1) the United States Pharmacopeia or the National Formulary; (2) USAN and the USP Dictionary of Drug Names; (3) CTFA Cosmetic Ingredient Dictionary; (4) Food Chemicals Codex. An ingredient not listed in any of the aforementioned reference works should be identified by its common or usual name (the name generally recognized by consumers or health-care professionals) or, if no common or usual name is available, by its chemical or other technical name.

An ingredient that may be, but not always is, present in a product should be qualified by words such as "or" or "may also contain."

The name of an ingredient whose identity is a trade secret may be omitted from the list if the list states "and other ingredients." For the purposes of this guideline, an ingredient is considered to be a trade secret only if its presence confers a significant competitive advantage upon its manufacturer and if its identity cannot be ascertained by the use of modern analytical technology.

An incidental trace ingredient having no functional or technical effect on the product need not be listed unless it has been demonstrated to cause sensitivity reactions or allergic responses.

Inactive ingredients should be listed on the label of a container of a product intended for sale without prescription, except that in the case of a container that is too small, such information may be contained in other labeling on or within the package.

Auxiliary Information— Please [check for your question in the FAQs](#) before contacting USP.

#### 1092 THE DISSOLUTION PROCEDURE: DEVELOPMENT AND VALIDATION

The USP dissolution procedure is a performance test applicable to many dosage forms. It is one test in a series of tests that constitute the dosage form's public specification (tests, procedures for the tests, acceptance criteria). To satisfy the performance test, USP provides the general test chapters [Disintegration](#) 701, [Dissolution](#) 711, and [Drug Release](#) 724. These chapters provide information about conditions of the procedure. For dissolution, these include information about (1) medium, (2) apparatus/agitation rate, (3) study design, (4) assay, and (5) acceptance criteria. Overall the dissolution procedure yields data to allow an accept/reject decision relative to the acceptance criteria, which are frequently based on a regulatory decision. This chapter provides recommendations on how to develop and validate a dissolution procedure.

##### GENERAL COMMENTS

The dissolution procedure requires an apparatus, a dissolution medium, and test conditions that provide a method that is discriminating yet sufficiently rugged and reproducible for day-to-day operation and capable of being transferred between laboratories.

The acceptance criteria should be representative of multiple batches with the same nominal composition and manufacturing process, typically including key batches used in pivotal studies, and representative of performance in stability studies.

The procedure should be appropriately discriminating, capable of distinguishing significant changes in a composition or manufacturing process that might be expected to affect in vivo performance. It is also possible for the procedure to show differences between batches when no significant difference is observed in vivo. This situation requires careful evaluation of whether the procedure is too sensitive or appropriately discriminating. Assessing the results from multiple batches that represent typical variability in composition and manufacturing parameters may assist in this evaluation. It is sometimes valuable to intentionally vary manufacturing parameters, such as lubrication, blend time, compression force, or drying parameters, to further characterize the discriminatory power of the procedure.

With regard to stability, the dissolution test should appropriately reflect relevant changes in the drug product over time that are caused by temperature, humidity, photosensitivity, and other stresses.

A properly designed test should result in data that are not highly variable and should not be associated with significant analytical solution stability problems. High variability in results can make it difficult to identify trends or effects of formulation changes. Dissolution results may be considered highly variable if the relative standard deviation (RSD) is greater than 20% at time points of 10 minutes or less and greater than 10% RSD at later time points.<sup>4</sup> However, most dissolution results exhibit less variability than this. The source of the variability should be investigated when practical, and attempts should be made to reduce variability whenever possible. The two most likely causes are the formulation itself (e.g., drug substance, excipients, or manufacturing process) or artifacts associated with the test procedure (e.g., coning, tablets sticking to the vessel wall or basket screen). Visual observations are often helpful for understanding the source of the variability and whether the dissolution test itself is contributing to the variability. Any time the dosage contents do not disperse freely throughout the vessel in a uniform fashion, aberrant results can occur. Depending on the problem, the usual remedies include changing the apparatus type, speed of agitation, or deaeration; consideration and/or examination of sinker type; and changing the composition of the medium. Modifications to the apparatus may also be useful, with proper justification and validation.

Many causes of variability can be found in the formulation and manufacturing process. For example, poor content uniformity, process inconsistencies, a reaction taking place at different rates during dissolution, excipient interactions or interference, film coating, capsule shell aging, and hardening or softening of the dosage form on stability may be sources of variability and interferences. During routine testing of the product, variability outside the expected range should be investigated from analytical, formulation, and processing perspectives.

##### MEDIUM

Physical and chemical data for the drug substance and dosage unit need to be determined before selecting the dissolution medium. Two key properties of the drug are the solubility

... solution state stability of the drug as a function of the pH value. When selecting the composition of the medium, the influence of buffers, pH value, and surfactants on the solubility and stability of the drug need to be evaluated. Key properties of the dosage unit that may affect dissolution include release mechanism (immediate, delayed, or modified) and disintegration rate as affected by hardness, friability, presence of solubility enhancers, and presence of other excipients.

Generally, when developing a dissolution procedure, one goal is to have sink conditions, defined as the volume of medium at least three times that required in order to form a saturated solution of drug substance. When sink conditions are present, it is more likely that dissolution results will reflect the properties of the dosage form. A medium that fails to provide sink conditions may be acceptable if it is shown to be more discriminating or otherwise appropriately justified.

Using an aqueous-organic solvent mixture as a dissolution medium is discouraged; however, with proper justification this type of medium may be acceptable.

Purified water is often used as the dissolution medium, but is not ideal for several reasons. First, the quality of the water can vary depending on the source of the water, and the pH value of the water is not controlled. Second, the pH value can vary from day to day and can also change during the run, depending on the active substance and excipients. Despite these limitations, water is inexpensive, readily available, easily disposed of, ecologically acceptable, and suitable for products with a release rate independent of the pH value of the medium.

The dissolution characteristics of an oral formulation should be evaluated in the physiologic pH range of 1.2 to 6.8 (1.2 to 7.5 for modified-release formulations). During method development, it may be useful to measure the pH before and after a run to discover whether the pH changes during the test. Selection of the most appropriate conditions for routine testing is then based on discriminatory capability, ruggedness, stability of the analyte in the test medium, and relevance to in vivo performance, where possible.

Typical media for dissolution may include the following (not listed in order of preference): dilute hydrochloric acid, buffers in the physiologic pH range of 1.2 to 7.5, simulated gastric or intestinal fluid (with or without enzymes), water, and surfactants (with or without acids or buffers) such as polysorbate 80, sodium lauryl sulfate, and bile salts.

The molarity of the buffers and acids used can influence the solubilizing effect, and this factor may be evaluated.

For compounds with high solubility and high permeability (as defined by the Biopharmaceutics Classification System), the choice of medium and apparatus may be influenced by the referenced FDA Guidance<sup>4</sup>.

For very poorly soluble compounds, aqueous solutions may contain a percentage of a surfactant (e.g., sodium lauryl sulfate, polysorbate, or lauryldimethylamine oxide) that is used to enhance drug solubility. The need for surfactants and the concentrations used can be justified by showing profiles at several different concentrations. Surfactants can be used either as wetting agents or to solubilize the drug substance.

#### Volume

Normally, for basket and paddle apparatus, the volume of the dissolution medium is 500 mL to 1000 mL, with 900 mL as the most common volume. The volume can be raised to between 2 and 4 L, using larger vessels and depending on the concentration and sink conditions of the drug; justification for this procedure is expected.

#### Deareration

The significance of deareration of the medium should be determined, because air bubbles can interfere with the test results, acting as a barrier to dissolution if present on the dosage unit or basket mesh. Further, bubbles can cause particles to cling to the apparatus and vessel walls. On the other hand, bubbles on the dosage unit may increase buoyancy, leading to an increase in the dissolution rate, or may decrease the available surface area, leading to a decrease in the dissolution rate. A deareration method is described as a footnote in the Procedure section under [Dissolution](#) (711). Typical steps include heating the medium, filtering, and drawing a vacuum for a short period of time. Other methods of deareration are available and in routine use throughout the industry. Media containing surfactants are not usually dearerated because the process results in excessive foaming. To determine whether deareration of the medium is necessary, results from dissolution samples run in nondearated medium and dearerated medium should be compared.

#### Enzymes

The use of enzymes in the dissolution medium is permitted in accordance with [Dissolution](#) (711) when dissolution failures occur as a result of cross-linking with gelatin capsules or gelatin-coated products.

#### In Vitro-In Vivo Correlation (IVIVC)

An in-depth discussion on IVIVC can be found in [In Vitro and In Vivo Evaluation of Dosage Forms](#) (1088). A brief discussion follows.

Biorelevant medium is a medium that has some relevance to the in vivo performance of the dosage unit. Choice of a biorelevant medium is based on (1) a mechanistic approach that considers the absorption site, if known, and (2) whether the rate-limiting step to absorption is the dissolution or permeability of the compound. In some cases, the biorelevant medium will be different from the test conditions chosen for the regulatory test, and the time points are also likely to be different. If the compound dissolves quickly in the stomach and is highly permeable, gastric emptying time may be the rate-limiting step to absorption. In this case, the dissolution test should demonstrate that the drug is released quickly under typical gastric (acidic) conditions. On the other hand, if dissolution occurs primarily in the intestinal tract (e.g., for a poorly soluble, weak acid), a higher pH range (e.g., simulated intestinal fluid with a pH of 6.8) may be more appropriate. The fed and fasted states may also have significant effects on the absorption or solubility of a compound. Compositions of media that simulate the fed and fasted states can be found in the literature. These media reflect changes in pH, bile concentrations, and osmolarity after meal intake and therefore have a composition different from that of typical compendial media. They are primarily used to establish in vitro-in vivo correlations during formulation development and to assess potential food effects and are not intended for quality control purposes. For quality control purposes, the substitution of natural surfactants (bile components) with appropriate synthetic surfactants is permitted and encouraged because of the expense of the natural substances and the labor-intensive preparation of the biorelevant media.

#### APPARATUS/AGITATION

##### Apparatus

The choice of apparatus is based on knowledge of the formulation design and the practical aspects of dosage form performance in the in vitro test system. For solid oral dosage forms, Apparatus 1 and Apparatus 2 are used most frequently.

When Apparatus 1 or 2 is not appropriate, another official apparatus may be used. Apparatus 3 (Reciprocating Cylinder) has been found to be especially useful for bead-type modified-release dosage forms. Apparatus 4 (Flow-Through Cell) may offer advantages for modified-release dosage forms that contain active ingredients with limited solubility. In addition, Apparatus 3 or Apparatus 4 may have utility for soft gelatin capsules, bead products, suppositories, or poorly soluble drugs. Apparatus 5 (Paddle over Disk) and Apparatus 6 (Rotating Cylinder) have been shown to be useful for evaluating and testing transdermal dosage forms. Apparatus 7 (Reciprocating Holder) has been shown to have application to nondisintegrating oral modified-release dosage forms, as well as to transdermal dosage forms.

Some changes can be made to the apparatus; for example, a basket mesh size other than the typical 40-mesh basket (e.g., 10, 20, 80 mesh) may be used when the need is clearly documented by supporting data. In countries where available mesh sizes vary from the USP-specified mesh value, basket material with the nearest metric dimension should be used.

Care must be taken that baskets are uniform and meet the dimensional requirements specified under [Dissolution](#) (711). If the basket screens become clogged during dissolution of capsule or tablet formulations, it may be advisable to switch to the paddle method. The volume can be increased from the typical 900 to 1000 mL by using 2- and 4-L vessels to assist in meeting sink conditions for poorly soluble drugs.

A noncompendial apparatus may have some utility with proper justification, qualification, and documentation of superiority over the standard equipment. For example, a small-volume apparatus with mini paddles and baskets may be considered for low-dosage strength products. The rotating bottle or static tubes (jacketed stationary tubes enclosed with a water jacket and equipped with a magnetic stirrer) may also have utility for microspheres and implants, peak vessels for eliminating coning, and modified flow-through cells for special dosage forms, including powders and stents.

#### Sinkers

When sinkers are used, a detailed description of the sinker must be stated in the written procedure. It may be useful to evaluate different sinkers, recognizing that sinkers can

significantly influence the dissolution profile of a dosage unit. When transferring the procedure, the sinkers should be duplicated as closely as possible in the next facility. There are several types of commercially available sinkers. A method for making sinkers by hand, sinkers that are similar to "a few turns of wire helix" as described in Apparatus 2 (Paddle Apparatus) under [Dissolution](#) (711), is described below.

Materials— Use 316 stainless steel wire or other inert material, typically 0.032 inch/20 gauge; and cylinders of appropriate diameter (e.g., cork borers). Sizes are shown in the accompanying table.

Capsule Shell Type	Length of Wire (cm)	Diameter (cm)	Cork Bore Number
#0, elongated	12	0.8	4
#1 and #2	10	0.7	3
#3 and #4	8	0.55	2

Procedure— Cut the specified length of wire, coil around a cylinder of the appropriate size, and use small pliers to curve in the ends. Use caution, because wire ends may be rough and may need to be filed.

If the sinker is handmade, the sinker material and construction procedure instructions should be documented; if a commercial sinker is used, the vendor part number should be reported.

#### Agitation

For immediate-release capsule or tablet formulations, Apparatus 1 (baskets) at 100 rpm or Apparatus 2 (paddles) at 50 or 75 rpm are most commonly used. Other agitation speeds and apparatus are acceptable with appropriate justification.

Rates outside 25 to 150 rpm are usually inappropriate because of the inconsistency of hydrodynamics below 25 rpm and because of turbulence above 150 rpm. Agitation rates between 25 and 50 rpm are generally acceptable for suspensions. For dosage forms that exhibit coning (mounding) under the paddle at 50 rpm, the coning can be reduced by increasing the paddle speed to 75 rpm, thus reducing the artifact and improving the data. If justified, 100 rpm may be used, especially for extended-release products. Decreasing or increasing the apparatus rotation speed may be justified if the profiles better reflect *in vivo* performance and/or the method results in better discrimination without adversely affecting method reproducibility.

Selection of the agitation and other study design elements for modified-release dosage forms is similar to that for immediate-release products. These elements should conform to the requirements and specifications given in [Dissolution](#) (711) when the apparatus has been appropriately calibrated.

#### STUDY DESIGN

##### Time Points

For immediate-release dosage forms, the duration of the procedure is typically 30 to 60 minutes; in most cases, a single time point specification is adequate for Pharmacopeial purposes. Industrial and regulatory concepts of product comparability and performance may require additional time points, which may also be required for product registration or approval. A sufficient number of time points should be selected to adequately characterize the ascending and plateau phases of the dissolution curve. According to the Biopharmaceutics Classification System referred to in several FDA Guidance, highly soluble, highly permeable drugs formulated with rapidly dissolving products need not be subjected to a profile comparison if they can be shown to release 85% or more of the active drug substance within 15 minutes. For these types of products a one-point test will suffice. However, most products do not fall into this category. Dissolution profiles of immediate-release products typically show a gradual increase reaching 85% to 100% at about 30 to 45 minutes. Thus, dissolution time points in the range of 15, 20, 30, 45, and 60 minutes are usual for most immediate-release products. For rapidly dissolving products, including suspensions, useful information may be obtained from earlier points, e.g., 5 to 10 minutes. For slower-dissolving products, time points later than 60 minutes may be useful. Dissolution test times for compendial tests are usually established on the basis of an evaluation of the dissolution profile data.

So-called infinity points can be useful during development studies. To obtain an infinity point, the paddle or basket speed is increased at the end of the run for a sustained period (typically 15 to 60 minutes), after which time an additional sample is taken. Although there is no requirement for 100% dissolution in the profile, the infinity point can provide data that may supplement content uniformity data and may provide useful information about formulation characteristics during initial development or about method bias.

For an extended-release dosage form, at least three test time points are chosen to characterize the *in vitro* drug release profile for Pharmacopeial purposes. Additional sampling times may be required for drug approval purposes. An early time point, usually 1 to 2 hours, is chosen to show that there is little probability of dose dumping. An intermediate time point is chosen to define the *in vitro* release profile of the dosage form, and a final time point is chosen to show the essentially complete release of the drug. Test times and specifications are usually established on the basis of an evaluation of drug release profile data. For products containing more than a single active ingredient, drug release is to be determined for each active ingredient.

##### Observations

Visual observations and recordings of product dissolution and disintegration behavior are very useful because dissolution and disintegration patterns can be indicative of variables in the formulation or manufacturing process. To accomplish visual observation, proper lighting (with appropriate consideration of photodegradation) of the vessel contents and clear visibility in the bath are essential. Documenting observations by drawing sketches and taking photographs or videos can be instructive and helpful for those who are not able to observe the real time dissolution test. Observations are especially useful during method development and formulation optimization. Examples of typical observations include, but are not limited to, the following:

1. Uneven distribution of particles throughout the vessel. This can occur when particles cling to the sides of the vessel, when there is coning or mounding directly under the apparatus, when particles float at the surface of the medium, when film-coated tablets stick to the vessel, and/or when off-center mounds are formed.
2. Air bubbles on the inside of the vessel or on the apparatus or dosage unit. Sheen on the apparatus is also a sign of air bubbles. This observation would typically be made when assessing the need to deaerate the medium.
3. Dancing or spinning of the dosage unit, or the dosage unit being hit by the paddle.
4. Adhesion of particles to the paddle or the inside of the basket, which may be observed upon removal of the stirring device at the end of the run.
5. Pellicles or analogous formations, such as transparent sacs or rubbery, swollen masses surrounding the capsule contents.
6. Presence of large floating particles or chunks of the dosage unit.
7. Observation of the disintegration rate (e.g., percentage reduction in size of the dosage unit within a certain time frame).
8. Complex disintegration of the coating of modified or enteric-coated products—for example, the partial opening and splitting apart (like a clamshell) or incomplete opening of the shell accompanied by the release of air bubbles and excipients.

##### Sampling

Manual— Manual sampling uses plastic or glass syringes, a stainless steel cannula that is usually curved to allow for vessel sampling, a filter, and/or a filter holder. The sampling site must conform to specifications under [Dissolution](#) (711).

Autosampling— Autosampling is a useful alternative to manual sampling, especially if the test includes several time points. However, because regulatory labs may perform the dissolution test using manual sampling, autosampling requires validation with manual sampling.

There are many brands of autosamplers, including semiautomated and fully automated systems. Routine performance checks, cleaning, and maintenance as described in the pertinent standard operating procedures or metrology documents are useful for reliable operation of these devices.

Some instruments are equipped with sampling through the basket or paddle shaft. Proper validation (e.g., demonstrated equivalence to results with the usual sampling procedure) may be required.

The disturbance of the hydrodynamics of the vessel by sampling probes should be considered and adequate validation performed to ensure that the probes are not introducing a significant change in the dissolution rate.

Comparison of manual and automated procedures should be performed to evaluate the interchangeability of the procedures. This can be accomplished by comparing data from separate runs or, in some cases, by sampling both ways from the same vessel. Results should be consistent with the requirements for intermediate precision (described in this chapter in Validation) if the procedures are to be considered interchangeable.

Other aspects of automation validation may include carryover of residual drug, effect of an in-residence probe (simultaneous sampling as mentioned above may not be suitable in this case), adsorption of drug, and cleaning and/or rinse cycles.

#### Filters

Filtration of the dissolution samples is usually necessary to prevent undissolved drug particles from entering the analytical sample and further dissolving. Also, filtration removes insoluble excipients that may otherwise cause high background or turbidity. Prewetting of the filter with the medium may be necessary.

Filters can be in-line or at the end of the sampling probe or both. The pore size can range from 0.45 to 70  $\mu\text{m}$ . The usual types of filters are depth, disk, and flow-through. However, if the excipient interference is high, if the filtrate has a cloudy appearance, or if the filter becomes clogged, an alternative type of filter or pore size should be evaluated.

Adsorption of the drug(s) onto the filter needs to be evaluated. If drug adsorption occurs, the amount of initial filtrate discarded may need to be increased. If results are still unsuitable, an alternative filter material may be sought.

Filter validation may be accomplished by preparing a suitable standard solution or a completely dissolved sample solution (e.g., prepared as a typical sample in a vessel or a sample put in a beaker and stirred with a magnetic stirrer for 1 hour). For standard solutions, compare the results for filtered solutions (after discarding the appropriate volume) to those for the unfiltered solutions. For sample solutions, compare the results for filtered solutions (after discarding the appropriate volume) to those for centrifuged, unfiltered solutions.

#### Centrifugation

Centrifugation of samples is not preferred, because dissolution can continue to occur and because there may be a concentration gradient in the supernatant. A possible exception might be for compounds that adsorb onto all common filters.

#### ASSAY

The usual assay for a dissolution sample is either spectrophotometric determination or HPLC. The preferred method of analysis is spectrophotometric determination because results can be obtained faster, the analysis is simpler, and fewer solvents are used. HPLC methods are used when there is significant interference from excipients or among drugs in the formulation to improve analytical sensitivity and/or when the analysis can be automated. It may be useful to obtain data for the drug with a stability-indicating assay (e.g., HPLC chromatograms) in the medium of choice, even if the primary assay is based on a spectrophotometric method.

#### VALIDATION

The validation topics described in this section are typical but not all-inclusive. The validation elements addressed may vary, depending on the phase of development or the intended use for the data.<sup>2</sup> The acceptance criteria are presented as guidelines only and may differ for some products. Firms should document the appropriate acceptance criteria for their products in pertinent SOPs. Other considerations may be important for special dosage forms. The extent of validation depends on the phase of the product development. Full validation takes place by the time of Phase III clinical studies. Validation studies should address the variations associated with different profile time points. For products containing more than a single active ingredient, the dissolution method needs to be validated for each active ingredient.

##### Specificity/Placebo Interference

It is necessary to demonstrate that the results are not unduly affected by placebo constituents, other active drugs, or degradates.

The placebo consists of all the excipients and coatings (inks, sinker, and capsule shell are also included when appropriate) without the active ingredient. Placebo interference may be determined by weighing samples of the placebo blend and dissolving or dispersing them in dissolution medium at concentrations that would be encountered during testing. It may be desirable to perform this experiment at 37° by comparing it to the 100% standard by the formula:

$$100C(AP / AS)(V/L)$$

in which C is the concentration, in mg per mL, of the standard; AP and AS are the absorbances of the placebo and the standard, respectively; V is the volume, in mL, of the medium; and L is the label claim, in mg. The interference should not exceed 2%.

note—For extended-release products, a placebo version of the finished dosage form may be more appropriate to use than blends, because this placebo formulation will release the various excipients in a manner more nearly reflecting the product than will a simple blend of the excipients. In this case, it may be appropriate to evaluate potential interference at multiple sampling points in the release profile.

If the placebo interference exceeds 2%, then method modification—such as (1) choosing another wavelength, (2) baseline subtraction using a longer wavelength, or (3) using HPLC—may be necessary in order to avoid the interference. When other active drugs or significant levels of degradates are present, it is necessary to demonstrate that these do not significantly affect the results. One procedure for doing this is to measure the matrix in the presence and absence of the other active drug or degradate: any interference should not exceed 2%.

##### Linearity and Range

Linearity and range are typically established by preparing solutions of the drug, ranging in concentration from below the lowest expected concentration to above the highest concentration during release. This may be done in conjunction with accuracy/recovery determination. The scheme may be altered if different flow-cell sizes or injection volumes are used.

Typically, solutions are made from a common stock if possible. For the highest concentration, the determination may not exceed the linearity limits of the instrument.

Organic solvents may be used to enhance drug solubility for the preparation of the standard solutions; however, no more than 5% (v/v) of organic solvent in the final solution should be used, unless validated.

Linearity is typically calculated by using an appropriate least-squares regression program. Typically, a square of the correlation coefficient ( $r^2 \geq 0.98$ ) demonstrates linearity. In addition, the y-intercept must not be significantly different from zero.

##### Accuracy/Recovery

Accuracy/recovery are typically established by preparing multiple samples containing the drug and any other constituents present in the dosage form (e.g., excipients, coating materials, capsule shell) ranging in concentration from below the lowest expected concentration to above the highest concentration during release.

In cases of poor drug solubility, it may be appropriate to prepare a stock solution by dissolving the drug substance in a small amount of organic solvent (typically not exceeding 5%) and diluting to the final concentration with dissolution medium. An amount of stock solution equivalent to the targeted label claim may be added to the vessel instead of the drug powder. Similarly, for very low strengths, it may be more appropriate to prepare a stock solution than to attempt to weigh very small amounts. The measured recovery is typically 95% to 105% of the amount added. Bracketing or matrixing of multiple strengths may be useful.

A special case for validation is the Acid Stage procedure described in Delayed-Release Dosage Forms under [Dissolution](#) 711. The limit of not more than 10% needs to be validated. If the compound degrades in acid, the validation experiment must address this fact.

#### Precision

Repeatability— Repeatability is determined by replicate measurements of standard and/or sample solutions. It can be measured by calculating the RSD of the multiple injections or spectrophotometric readings for each standard solution, or from the accuracy or linearity data.

Intermediate Precision— Intermediate precision may be evaluated to determine the effects of random events on the precision of the analytical procedure. This evaluation is typically done later in the development of the drug product. The precision can be across the range of product strengths. Typical variations to study include days, analysts, and equipment. The use of an experimental matrix design is encouraged for evaluation of intermediate precision. If possible, intermediate precision can be evaluated using a well-characterized lot of drug product of tight content uniformity. In cases where a well-characterized product is not available, placebo and active ingredient may be used to identify intermediate precision.

The dissolution profiles on the same sample may be run by at least two different analysts, each analyst preparing the standard solutions and the medium. Typically, the analysts use different dissolution baths, spectrophotometers or HPLC equipment (including columns), and autosamplers; and they perform the test on different days. This procedure may not need to be performed for each strength; instead, bracketing with high and low strengths may be acceptable.

A typical acceptance criterion is that the difference in the mean value between the dissolution results at any two conditions using the same strength does not exceed an absolute 10% at time points with less than 85% dissolved and does not exceed 5% for time points above 85%. Acceptance criteria may be product-specific, and other statistical tests and limits may be used.

#### Robustness

The evaluation of robustness, which assesses the effect of making small, deliberate changes to the dissolution conditions, typically is done later in the development of the drug product. The number of replicates (typically 3 or 6) is dependent on the intermediate precision.

Parameters to be varied are dependent on the dissolution procedure and analysis type. They may include medium composition (e.g., buffer or surfactant concentration), pH, volume, agitation rate, and temperature. For HPLC analysis, parameters may include mobile phase composition (percentage organic, buffer concentration, pH), flow rate, wavelength, column temperature, and multiple columns (of the same type). For spectrophotometric analysis, the wavelength may be varied.

#### Standard and Sample Solution Stability

The standard solution is stored under conditions that ensure stability. The stability of the standard is analyzed over a specified period of time, using a freshly prepared standard solution at each time interval for comparison. The acceptable range for standard solution stability is typically between 98% and 102%.

The sample solution is typically stored at room temperature. The sample is analyzed over a specified period of time using the original sample solution response for comparison. The typical acceptable range for sample solution stability may be between 98% and 102% compared with the initial analysis of the sample solutions. If the solution is not stable, aspects to consider could be temperature (refrigeration may be needed), light protection, and container material (plastic or glass).

The procedure may state that the standards and samples need to be analyzed within a time period demonstrating acceptable standard and sample solution stability.

#### Spectrophotometric Analysis

Samples may be automatically introduced into the spectrophotometer using autosippers and flow cells. Routine performance checks, cleaning, and maintenance as described in the standard operating procedures or metrology documents are useful for reliable operation of these instruments. Cells with path lengths ranging from 0.02 to 1 cm are typically used. Cell alignment and air bubbles could be sources of error. The smaller path length cells are used to avoid diluting the sample; however, acceptable linearity and standard error need to be demonstrated.

During analysis, standard solutions are typically prepared and analyzed at just one concentration at 100% (or the selected Q value) of the dosage strength. During profile analysis, other concentrations may be useful. A typical blank, standard, and sample may be analyzed in a sequence that brackets the sample with standards and blanks, especially at the beginning and end of the analysis.

In most cases, the mean absorbance of the dissolution medium blank may not exceed 1% of the standard. Values higher than 1% must be evaluated on a case-by-case basis. The typical RSD for UV analysis is usually not more than 2%.

The absorptivity is calculated by dividing the mean standard absorbance by the concentration, in mg per mL, divided by the flow-cell path length in cm. After enough historical data are accumulated, an acceptable absorptivity range for the analyte (using the appropriate flow cell) may be determined. This value may be useful in troubleshooting aberrant data.

Fiber optics as a sampling and determinative method, with proper validation, is an option.

It may be useful to examine the UV spectrum of the drug in solution to select the optimum wavelength.

#### HPLC

For HPLC analysis, the compatibility of dissolution media and mobile phase may be examined, especially if large injector volumes (over 100  $\mu$ L) are needed. Samples are normally analyzed with HPLC using a spectrophotometric detector and an auto-injector. Single injections of each vessel time point with standards throughout the run constitute a typical run design. System suitability tests include, at a minimum, the retention window and injection precision. Typically, the repeatability of an HPLC analysis should be less than or equal to 2% RSD for five or six standard determinations. The standard level is typically at the 100% label claim level, especially for a single-point analysis.

Preparation of the placebo samples for the HPLC analysis is to be performed in the same way as in the spectrophotometric analysis. Examine the chromatogram for peaks eluting at the same retention time as the drug. If there are extraneous peaks, inject the standard solution, and compare retention times. If the retention times are too close, spike the placebo solution with the drug. Chromatograms may also be obtained over an extended run time using the blank (dissolution medium), standard, and sample solution to identify late eluters that may interfere with subsequent analyses.

The validation documentation may include overlaid representative chromatograms or spectra of blank dissolution medium, a filtered placebo solution, a standard solution, and a filtered dissolution sample. Absence of interfering peaks in the placebo chromatogram or lack of absorbance by the placebo at the analytical wavelength demonstrates specificity.

#### ACCEPTANCE CRITERIA

Typical acceptance criteria for the amount of active ingredient dissolved, expressed as a percentage of the labeled content (Q), are in the range of 75% to 80% dissolved. A Q value in excess of 80% is not generally used, because allowance needs to be made for assay and content uniformity ranges.<sup>3</sup> Acceptance criteria including test times are usually established on the basis of an evaluation of the dissolution profile data. Acceptance criteria should be consistent with historical data, and there is an expectation that acceptable batches (e.g., no significant differences in *in vivo* performance, composition, or manufacturing procedure) will have results that fall within the acceptance criteria.

1 The Biopharmaceutics Classification System is outlined in the FDA Guidance for Industry: Waiver of In Vivo Bioavailability and Bioequivalence Studies for Immediate-Release Solid Oral Dosage Forms Based on a Biopharmaceutics Classification System, August 2000; <http://www.fda.gov/cder/guidance/3618fnl.htm>, accessed 6/22/2005.

**1101 MEDICINE DROPPER**

The Pharmacopeial medicine dropper consists of a tube made of glass or other suitable transparent material that generally is fitted with a collapsible bulb and, while varying in capacity, is constricted at the delivery end to a round opening having an external diameter of about 3 mm. The dropper, when held vertically, delivers water in drops each of which weighs between 45 mg and 55 mg.

In using a medicine dropper, one should keep in mind that most medicinal liquids do not have the same surface tension and viscosity characteristics as water, and therefore the size of drops will vary from one preparation to another.

Where accuracy of dosage is important, a dropper that has been calibrated specifically for the preparation with which it is supplied should be employed. The volume error incurred in measuring any liquid by means of a calibrated dropper should not exceed 15% under normal use conditions.

**1111 MICROBIOLOGICAL ATTRIBUTES OF NONSTERILE PHARMACEUTICAL PRODUCTS**

Few raw materials used in making pharmaceutical products are sterile as received, and special treatment may be required to render them microbiologically acceptable for use. Strict adherence to effective environmental control and sanitation, equipment cleaning practices, and good personal hygiene practices in pharmaceutical manufacture is vital in minimizing both the type and the number of microorganisms.

Monitoring, in the form of regular surveillance, should include an examination of the microbiological attributes of Pharmacopeial articles and a determination of compliance with such microbiological standards as are set forth in the individual monographs. It may be necessary also to monitor the early and intermediate stages of production, with emphasis being placed on raw materials, especially those of animal or botanical origin, or from natural mineral sources, which may harbor objectionable microorganisms not destroyed during subsequent processing. It is essential that ingredients and components be stored under conditions designed to deter microbial proliferation.

The nature and frequency of testing vary according to the product. Monographs for some articles require freedom from one or more species of selected indicator microorganisms such as *Salmonella* species, *Escherichia coli*, *Staphylococcus aureus*, and *Pseudomonas aeruginosa*. For some articles, a specific limit on the total aerobic count of viable microorganisms and/or the total combined molds and yeasts count is set forth in the individual monograph; in these cases a requirement for freedom from specified indicator microorganisms may also be included. The significance of microorganisms in nonsterile pharmaceutical products should be evaluated in terms of the use of the product, the nature of the product, and the potential hazard to the user. Also taken into account is the processing of the product in relation to an acceptable quality for pharmaceutical purposes.

It is suggested that certain categories of products should be tested routinely for total microbial count and for specified indicator microbial contaminants, e.g., natural plant, animal, and some mineral products for *Salmonella* species; oral solutions and suspensions for *E. coli*; articles applied topically for *P. aeruginosa* and *S. aureus*; and articles intended for rectal, urethral, or vaginal administration for yeasts and molds.

Definitive microbial limits (stipulated microorganisms and/or counts) are incorporated into specific monographs on the basis of a major criterion, i.e., the potential of the stipulated microorganisms and/or counts, and of any others that they may reflect, to constitute a hazard in the end product. Such considerations also take into account the processing to which the product components are subjected, the current technology for testing, and the availability of desired quality material. Any of these may preclude the items from specific requirements under [Microbial Enumeration Tests \(61\)](#) and [Tests for Specified Microorganisms \(62\)](#). Regardless of such preclusion, it remains essential to apply strict good manufacturing practices to assure a lowest possible load of microorganisms.

The relevant tests for determining the total count of viable aerobic microorganisms and the total combined molds and yeasts count, and for detection and identification of designated species are given under [Microbial Enumeration Tests \(61\)](#) and [Tests for Specified Microorganisms \(62\)](#). For reliable results, the personnel responsible for the conduct of the test should have specialized training in microbiology and in the interpretation of microbiological data.

**1111 MICROBIOLOGICAL EXAMINATION OF NONSTERILE PRODUCTS: ACCEPTANCE CRITERIA FOR PHARMACEUTICAL PREPARATIONS AND SUBSTANCES FOR PHARMACEUTICAL USE**

The presence of certain microorganisms in nonsterile preparations may have the potential to reduce or even inactivate the therapeutic activity of the product and has a potential to adversely affect the health of the patient. Manufacturers have therefore to ensure a low bioburden of finished dosage forms by implementing current guidelines on Good Manufacturing Practice during the manufacture, storage, and distribution of pharmaceutical preparations.

Microbial examination of nonsterile products is performed according to the methods given in the texts on [Microbial Enumeration Tests \(61\)](#) and [Tests for Specified Microorganisms \(62\)](#). Acceptance criteria for nonsterile pharmaceutical products based upon the total aerobic microbial count (TAMC) and the total combined yeasts and molds count (TYMC) are given in [Tables 1](#) and [2](#). Acceptance criteria are based on individual results or on the average of replicate counts when replicate counts are performed (e.g., direct plating methods).

When an acceptance criterion for microbiological quality is prescribed, it is interpreted as follows:

- 101 cfu: maximum acceptable count = 20;
- 102 cfu: maximum acceptable count = 200;
- 103 cfu: maximum acceptable count = 2000; and so forth.

Table 1. Acceptance Criteria for Microbiological Quality of Nonsterile Dosage Forms

Route of Administration	Total Aerobic Microbial Count (cfu/g or cfu/mL)	Total Combined Yeasts/Molds Count (cfu/g or cfu/mL)	Specified Microorganism(s)
Nonaqueous preparations for oral use	103	102	Absence of Escherichia coli (1 g or 1 mL)
Aqueous preparations for oral use	102	101	Absence of Escherichia coli (1 g or 1 mL)
Rectal use	103	102	—
Oromucosal use	102	101	Absence of Staphylococcus aureus (1 g or 1 mL) Absence of Pseudomonas aeruginosa (1 g or 1 mL)
Gingival use	102	101	Absence of Staphylococcus aureus (1 g or 1 mL) Absence of Pseudomonas aeruginosa (1 g or 1 mL)
Cutaneous use	102	101	Absence of Staphylococcus aureus (1 g or 1 mL) Absence of Pseudomonas aeruginosa (1 g or 1 mL)
Nasal use	102	101	Absence of Staphylococcus aureus (1 g or 1 mL) Absence of Pseudomonas aeruginosa (1 g or 1 mL)
Auricular use	102	101	Absence of Staphylococcus aureus (1 g or 1 mL) Absence of Pseudomonas aeruginosa (1 g or 1 mL)
Vaginal use	102	101	Absence of Pseudomonas aeruginosa (1 g or 1 mL) Absence of Staphylococcus aureus (1 g or 1 mL) Absence of Candida albicans (1 g or 1 mL)
Transdermal patches (limits for one patch including adhesive layer and backing)	102	101	Absence of Staphylococcus aureus (1 patch) Absence of Pseudomonas aeruginosa (1 patch)
Inhalation use (special requirements apply to liquid preparations for nebulization)	102	101	Absence of Staphylococcus aureus (1 g or 1 mL) Absence of Pseudomonas aeruginosa (1 g or 1 mL) Absence of bile-tolerant Gram-negative bacteria (1 g or 1 mL)

[Table 1](#) includes a list of specified microorganisms for which acceptance criteria are set. The list is not necessarily exhaustive, and for a given preparation it may be necessary to test for other microorganisms depending on the nature of the starting materials and the manufacturing process.

If it has been shown that none of the prescribed tests will allow valid enumeration of microorganisms at the level prescribed, a validated method with a limit of detection as close as possible to the indicated acceptance criterion is used.

Table 2. Acceptance Criteria for Microbiological Quality of Nonsterile Substances for Pharmaceutical Use

	Total Aerobic Microbial Count (cfu/g or cfu/mL)	Total Combined Yeasts/Molds Count (cfu/g or cfu/mL)
Substances for pharmaceutical use	103	102

In addition to the microorganisms listed in [Table 1](#), the significance of other microorganisms recovered should be evaluated in terms of the following:

- The use of the product: hazard varies according to the route of administration (eye, nose, respiratory tract).
- The nature of the product: does the product support growth? does it have adequate antimicrobial preservation?
  - The method of application.
  - The intended recipient: risk may differ for neonates, infants, the debilitated.
    - Use of immunosuppressive agents, corticosteroids.
    - The presence of disease, wounds, organ damage.

Where warranted, a risk-based assessment of the relevant factors is conducted by personnel with specialized training in microbiology and in the interpretation of microbiological data. For raw materials, the assessment takes account of the processing to which the product is subjected, the current technology of testing, and the availability of materials of the desired quality.

#### 1112 APPLICATION OF WATER ACTIVITY DETERMINATION TO NONSTERILE PHARMACEUTICAL PRODUCTS

The determination of the water activity of nonsterile pharmaceutical dosage forms aids in the decisions relating to the following:

- optimizing product formulations to improve antimicrobial effectiveness of preservative systems,
- reducing the degradation of active pharmaceutical ingredients within product formulations susceptible to chemical hydrolysis,
- reducing the susceptibility of formulations (especially liquids, ointments, lotions, and creams) to microbial contamination, and

- d. providing a tool for the rationale for reducing the frequency of microbial limit testing and screening for objectionable microorganisms for product release and stability testing, using methods contained in the general test chapter [Microbial Enumeration Tests](#) [61](#) and [Tests for Specified Microorganisms](#) [62](#).

Reduced water activity ( $a_W$ ) will greatly assist in the prevention of microbial proliferation in pharmaceutical products; and the formulation, manufacturing steps, and testing of nonsterile dosage forms should reflect this parameter.

Low water activity has traditionally been used to control microbial deterioration of foodstuffs. Examples where the available moisture is reduced are dried fruit, syrups, and pickled meats and vegetables. Low water activities make these materials self-preserved. Low water activity will also prevent microbial growth within pharmaceutical drug products. Other product attributes, for example, low or high pH, absence of nutrients, presence of surfactants, and addition of antimicrobial agents, as well as low water activity, help to prevent microbial growth. However, it should be noted that more resistant microorganisms, including spore-forming *Clostridium* spp., *Bacillus* spp., *Salmonella* spp. and filamentous fungi, although they may not proliferate in a drug product with a low water activity, may persist within the product.

When formulating an aqueous oral or topical dosage form, candidate formulations should be evaluated for water activity so that the drug product may be self-preserving, if possible. For example, small changes in the concentration of sodium chloride, sucrose, alcohol, propylene glycol, or glycerin in a formulation may result in the creation of a drug product with a lower water activity that can discourage the proliferation of microorganisms in the product. This is particularly valuable with a multiple-use product that may be contaminated by the user. Packaging studies should be conducted to test product stability and to determine that the container–closure system protects the product from moisture gains that would increase the water activity during storage.

Reduced microbial limits testing may be justified through risk assessment. This reduction in testing, when justified, may entail forgoing full microbial limits testing, implementing skip-lot testing, or eliminating routine testing.

Nonaqueous liquids or dry solid dosage forms will not support spore germination or microbial growth due to their low water activity. The frequency of their microbial monitoring can be determined by a review of the historic testing database of the product and the demonstrated effectiveness of microbial contamination control of the raw materials, ingredient water, manufacturing process, formulation, and packaging system. The testing history would include microbial monitoring during product development, scale-up, process validation, and routine testing of sufficient marketed product lots (e.g., up to 20 lots) to ensure that the product has little or no potential for microbial contamination. Because the water activity requirements for different Gram-reactive bacteria, bacterial spores, yeasts, and molds are well described in the literature,<sup>1</sup> the appropriate microbial limit testing program for products of differing water activities can be established. For example, Gram-negative bacteria including the specific objectionable microorganisms, *Pseudomonas aeruginosa*, *Escherichia coli*, and *Salmonella* species will not proliferate or survive in preserved products with water activities below 0.91, while Gram-positive bacteria such as *Staphylococcus aureus* will not proliferate below 0.86, and *Aspergillus niger* will not proliferate below 0.77. Furthermore, even the most osmophilic yeast and xerophilic fungi will not proliferate below 0.60, and they cannot be isolated on compendial microbiological media.<sup>1</sup> The water activity requirements measured at 25° for the growth of a range of representative microorganisms are presented in [Table 1](#).

Table 1. Water Activities ( $a_W$ ) Required to Support the Growth of Representative Microorganisms

Bacteria	Water Activity ( $a_W$ )	Molds and Yeast	Water Activity ( $a_W$ )
<i>Pseudomonas aeruginosa</i>	0.97	<i>Rhizopus nigricans</i>	0.93
<i>Bacillus cereus</i>	0.95	<i>Mucor plumbeus</i>	0.92
<i>Clostridium botulinum</i> , Type A	0.95	<i>Rhodotorula mucilaginosa</i>	0.92
<i>Escherichia coli</i>	0.95	<i>Saccharomyces cerevisiae</i>	0.90
<i>Clostridium perfringens</i>	0.95	<i>Paecilomyces variotti</i>	0.84
<i>Lactobacillus viridescens</i>	0.95	<i>Penicillium chrysogenum</i>	0.83
<i>Salmonella</i> spp.	0.95	<i>Aspergillus fumigatus</i>	0.82
<i>Enterobacter aerogenes</i>	0.94	<i>Penicillium glabrum</i>	0.81
<i>Bacillus subtilis</i>	0.90	<i>Aspergillus flavus</i>	0.78
<i>Micrococcus lysodekticus</i>	0.93	<i>Aspergillus niger</i>	0.77
<i>Staphylococcus aureus</i>	0.86	<i>Zygosachcharomyces rouxii</i> (osmophilic yeast)	0.62
<i>Halobacterium halobium</i> (halophilic bacterium)	0.75	<i>Xeromyces bisporus</i> (xerophilic fungi)	0.61

Pharmaceutical drug products with water activities well below 0.75 (e.g., direct compression tablets, powder and liquid-filled capsules, nonaqueous liquid products, ointments, and rectal suppositories) would be excellent candidates for reduced microbial limit testing for product release and stability evaluation. This is especially true when pharmaceutical products are made from ingredients of good microbial quality, when manufacturing environments do not foster microbial contamination, when there are processes that inherently reduce the microbial content, when the formulation of the drug product has antimicrobial activity, and when manufacturing sites have an established testing history of low bioburden associated with their products. [Table 2](#) contains suggested microbial limit testing strategies for typical pharmaceutical and over-the-counter (OTC) drug products based on water activity. Other considerations, as listed above, would be applied when setting up the microbial limits testing program for individual drug products because water activity measurements cannot solely be used to justify the elimination of microbial content testing for product release.

Similar arguments could be made for the microbial limits testing of pharmaceutical ingredients. However, this would require pharmaceutical manufacturers to have a comprehensive knowledge of the pharmaceutical ingredient manufacturer's manufacturing processes, quality programs, and testing record. This could be obtained through a supplier audit program.

Table 2. Microbial Limit Testing Strategy for Representative Pharmaceutical and OTC Drug Products Based on Water Activity

Products	Water Activity ( $a_W$ )	Greatest Potential Contaminants	Testing Recommended
Nasal inhalant	0.99	Gram-negative bacteria	TAMC,* TCYMC, absence of <i>S. aureus</i> and <i>P. aeruginosa</i>
Hair shampoo	0.99	Gram-negative bacteria	TAMC, TCYMC, absence of <i>S. aureus</i> and <i>P. aeruginosa</i>
Antacid	0.99	Gram-negative bacteria	TAMC, TCYMC, absence of <i>E. coli</i> and <i>Salmonella</i> spp.
Topical cream	0.97	Gram-positive bacteria	TAMC, TCYMC, absence of <i>S. aureus</i> and <i>P. aeruginosa</i>
Oral liquid	0.90	Gram-positive bacteria and fungi	TAMC and TCYMC
Oral suspension	0.87	Fungi	TAMC and TCYMC
Topical ointment	0.55	None	Reduced testing
Lip balm	0.36	None	Reduced testing
Vaginal and rectal suppositories	0.30	None	Reduced testing
Compressed tablets	0.36	None	Reduced testing
Liquid-filled capsule	0.30	None	Reduced testing

\* TAMC = Total aerobic microbial count; TCYMC = Total combined yeast and mold count.

note—The water activities cited in [Table 2](#) for the different dosage forms are representative, and companies are urged to test their individual products before developing a testing

Water activity,  $aW$ , is the ratio of vapor pressure of  $H_2O$  in product (P) to vapor pressure of pure  $H_2O$  ( $P_0$ ) at the same temperature. It is numerically equal to 1/100 of the relative humidity (RH) generated by the product in a closed system. RH can be calculated from direct measurements of partial vapor pressure or dew point or indirect measurement by sensors whose physical or electric characteristics are altered by the RH to which they are exposed.

The relationship between  $aW$  and equilibrium relative humidity (ERH) is represented by the following equations:

$$aW = P/P_0 \text{ and } ERH(\%) = aW \times 100$$

The  $aW$  measurement may be conducted using the dew point/chilled mirror method.<sup>2</sup> A polished, chilled mirror is used as the condensing surface. The cooling system is electronically linked to a photoelectric cell into which light is reflected from the condensing mirror. An air stream, in equilibrium with the test sample, is directed at the mirror which cools until condensation occurs on the mirror. The temperature at which this condensation begins is the dew point from which the ERH is determined. Sample preparation should be considered as it may affect the water activity level of the material tested. Commercially available instruments using the dew point/chilled mirror method or other technologies need to be evaluated for suitability, validated, and calibrated when used to make water activity determinations. These instruments are typically calibrated using saturated salt solutions at 25°, as listed in [Table 3](#).

Table 3. Standard Saturated Salt Solutions Used to Calibrate Water Activity Determination Instruments

Saturated Salt Solutions	ERH (%)	$aW$
Potassium sulfate ( $K_2SO_4$ )	97.3	0.973
Barium chloride ( $BaCl_2$ )	90.2	0.902
Sodium chloride ( $NaCl$ )	75.3	0.753
Magnesium nitrate ( $Mg(NO_3)_2$ )	52.9	0.529
Magnesium chloride ( $MgCl_2$ )	32.8	0.328

#### 1116 MICROBIOLOGICAL EVALUATION OF CLEAN ROOMS AND OTHER CONTROLLED ENVIRONMENTS

The purpose of this informational chapter is to review the various issues that relate to aseptic processing of bulk drug substances, dosage forms, and in certain cases, medical devices; and to the establishment, maintenance, and control of the microbiological quality of controlled environments.

This chapter includes discussions on (1) the classification of a clean room based on particulate count limits; (2) microbiological evaluation programs for controlled environments; (3) training of personnel; (4) critical factors in design and implementation of a microbiological evaluation program; (5) development of a sampling plan; (6) establishment of microbiological Alert and Action levels; (7) methodologies and instrumentation used for microbiological sampling; (8) media and diluents used; (9) identification of microbial isolates; (10) operational evaluation via media fills; and (11) a glossary of terms. Excluded from this chapter is a discussion of controlled environments for use by licensed pharmacies in the preparation of sterile products for home use, which is covered under [Pharmaceutical Compounding—Sterile Preparations](#) (797).

There are alternative methods to assess and control the microbiological status of controlled environments for aseptic processing. Numerical values included in this chapter are not intended to represent absolute values or specifications, but are informational. Given the variety of microbiological sampling equipment and methods, one cannot reasonably suggest that the attainment of these values guarantees the needed level of microbial control or that excursions beyond values in this chapter indicate a loss of control. The improper application of microbiological sampling and analysis may cause significant variability and the potential for inadvertent contamination. Sampling media and devices, and methods indicated in this chapter, are not specifications but only informational.

A large proportion of sterile products are manufactured by aseptic processing. Because aseptic processing relies on the exclusion of microorganisms from the process stream and the prevention of microorganisms from entering open containers during filling, product bioburden as well as microbial bioburden of the manufacturing environment are important factors relating to the level of sterility assurance of these products.

##### Establishment of Clean Room Classifications

The design and construction of clean rooms and controlled environments are covered in Federal Standard 209E. This standard of air cleanliness is defined by the absolute concentration of airborne particles. Methods used for the assignment of air classification of controlled environments and for monitoring of airborne particulates are included. This federal document only applies to airborne particulates within a controlled environment and is not intended to characterize the viable or nonviable nature of the particles.

The application of Federal Standard 209E to clean rooms and other controlled environments in the pharmaceutical industry has been used by manufacturers of clean rooms to provide a specification for building, commissioning, and maintaining these facilities. However, data available in the pharmaceutical industry provide no scientific agreement on a relationship between the number of nonviable particulates and the concentration of viable microorganisms.

The criticality of the number of nonviable particulates in the electronic industry makes the application of Federal Standard 209E a necessity, while the pharmaceutical industry has a greater concern for viable particulates (i.e., microorganisms) rather than total particulates as specified in Federal Standard 209E. A definite concern for counts of total particulates in injectable products exists in the pharmaceutical industry (see [Particulate Matter in Injections](#) (788)).

The rationale that the fewer particulates present in a clean room, the less likely it is that airborne microorganisms will be present is accepted and can provide pharmaceutical manufacturers and builders of clean rooms and other controlled environments with engineering standards in establishing a properly functioning facility.

Federal Standard 209E, as applied in the pharmaceutical industry is based on limits of all particles with sizes equal to or larger than 0.5  $\mu m$ . [Table 1](#) describes Airborne Particulate Cleanliness Classes in Federal Standard 209E as adapted to the pharmaceutical industry. The pharmaceutical industry deals with Class M3.5 and above. Class M1 and M3 relate to the electronic industry and are shown in [Table 1](#) for comparison purposes. It is generally accepted that if fewer particulates are present in an operational clean room or other controlled environment, the microbial count under operational conditions will be less, provided that there are no changes in airflow, temperature, and humidity. Clean rooms are maintained under a state of operational control on the basis of dynamic (operational) data.

Table 1. Airborne Particulate Cleanliness Classes\*

Class Name	Particles equal to and larger than 0.5 $\mu m$
U.S.	

SI	Customary	(m <sup>3</sup> )	(ft <sup>3</sup> )
M1	—	10.0	0.283
M1.5	1	35.3	1.00
M2	—	100	2.8
M2.5	10	353	10.0
M3	—	1,000	28.3
M3.5	100	3,530	100
M4	—	10,000	283
M4.5	1,000	35,300	1,000
M5	—	100,000	2,830
M5.5	10,000	353,000	10,000
M6	—	1,000,000	28,300
M6.5	100,000	3,530,000	100,000
M7	—	10,000,000	283,000

\* Adapted from U.S. Federal Standard 209E, September 11, 1992—"Airborne Particulate Cleanliness Classes in Clean Rooms and Clean Zones."

#### Importance of a Microbiological Evaluation Program for Controlled Environments

Monitoring of total particulate count in controlled environments, even with the use of electronic instrumentation on a continuous basis, does not provide information on the microbiological content of the environment. The basic limitation of particulate counters is that they measure particles of 0.5  $\mu\text{m}$  or larger. While airborne microorganisms are not free-floating or single cells, they frequently associate with particles of 10 to 20  $\mu\text{m}$ . Particulate counts as well as microbial counts within controlled environments vary with the sampling location and the activities being conducted during sampling. Monitoring the environment for nonviable particulates and microorganisms is an important control function because they both are important in achieving product compendial requirements for Particulate Matter and Sterility under [Injections](#) 1.

Microbial monitoring programs for controlled environments should assess the effectiveness of cleaning and sanitization practices by and of personnel that could have an impact on the bioburden of the controlled environment. Microbial monitoring, regardless of how sophisticated the system may be, will not and need not identify and quantitate all microbial contaminants present in these controlled environments. However, routine microbial monitoring should provide sufficient information to ascertain that the controlled environment is operating within an adequate state of control.

Environmental microbial monitoring and analysis of data by qualified personnel will permit the status of control to be maintained in clean rooms and other controlled environments. The environment should be sampled during normal operations to allow for the collection of meaningful data. Microbial sampling should occur when materials are in the area, processing activities are ongoing, and a full complement of operating personnel is on site.

Microbial monitoring of clean rooms and some other controlled environments, when appropriate, should include quantitation of the microbial content of room air, compressor air that enters the critical area, surfaces, equipment, sanitization containers, floors, walls, and personnel garments (e.g., gowns and gloves). The objective of the microbial monitoring program is to obtain representative estimates of bioburden of the environment. When data are compiled and analyzed, any trends should be evaluated by trained personnel. While it is important to review environmental results on the basis of recommended and specified frequency, it is also critical to review results over extended periods to determine whether trends are present. Trends can be visualized through the construction of statistical control charts that include alert and action levels. The microbial control of controlled environments can be assessed, in part, on the basis of these trend data. Periodic reports or summaries should be issued to alert the responsible manager.

When the specified microbial level of a controlled environment is exceeded, a documentation review and investigation should occur. There may be differences in the details of the investigation, depending on the type and processing of the product manufactured in the room. Investigation should include a review of area maintenance documentation; sanitization documentation; the inherent physical or operational parameters, such as changes in environmental temperature and relative humidity; and the training status of personnel involved. Following the investigation, actions taken may include reinforcement of training of personnel to emphasize the microbial control of the environment; additional sampling at increased frequency; additional sanitization; additional product testing; identification of the microbial contaminant and its possible source; and an evaluation of the need to reassess the current standard operating procedures and to revalidate them, if necessary.

Based on the review of the investigation and testing results, the significance of the microbial level being exceeded and the acceptability of the operations or products processed under that condition may be ascertained. Any investigation and the rationale for the course of action should be documented and included as part of the overall quality management system.

A controlled environment such as a clean zone or clean room is defined by certification according to a relevant clean room operational standard. Parameters that are evaluated include filter integrity, air velocity, air patterns, air changes, and pressure differentials. These parameters can affect the microbiological bioburden of the clean room operation. The design, construction, and operation of clean rooms varies greatly, making it difficult to generalize requirements for these parameters. An example of a method for conducting a particulate challenge test to the system by increasing the ambient particle concentration in the vicinity of critical work areas and equipment has been developed by Ljungquist and Reinmuller.<sup>1</sup> First, smoke generation allows the air movements to be visualized throughout a clean room or a controlled environment. The presence of vortices or turbulent zones can be visualized, and the airflow pattern may be fine-tuned to eliminate or minimize undesirable effects. Then, particulate matter is generated close to the critical zone and sterile field. This evaluation is done under simulated production conditions, but with equipment and personnel in place.

Proper testing and optimization of the physical characteristics of the clean room or controlled environment is essential prior to completion of the validation of the microbiological monitoring program. Assurance that the controlled environment is operating adequately and according to its engineering specifications will give a higher assurance that the bioburden of the environment will be appropriate for aseptic processing. These tests should be repeated during routine certification of the clean room or controlled environment and whenever changes made to the operation, such as personnel flow, processing, operation, material flow, air-handling systems, or equipment layout, are determined to be significant.

#### Training of Personnel

Aseptically processed products require manufacturers to pay close attention to detail and to maintain rigorous discipline and strict supervision of personnel in order to maintain the level of environmental quality appropriate for the sterility assurance of the final product.

Training of all personnel working in controlled environments is critical. This training is equally important for personnel responsible for the microbial monitoring program, where contamination of the clean working area could inadvertently occur during microbial sampling. In highly automated operations, the monitoring personnel may be the employees who have the most direct contact with the critical zones within the processing area. Monitoring of personnel should be conducted before or after working in the processing area.

Microbiological sampling has the potential to contribute to microbial contamination due to inappropriate sampling techniques. A formal personnel training program is required to minimize this risk. This formal training should be documented for all personnel entering controlled environments.

Management of the facility must assure that all personnel involved in operations in clean rooms and controlled environments are well versed in relevant microbiological principles. The training should include instruction on the basic principles of aseptic processing and the relationship of manufacturing and handling procedures to potential sources of product contamination. This training should include instruction on the basic principles of microbiology, microbial physiology, disinfection and sanitation, media selection and preparation, taxonomy, and sterilization as required by the nature of personnel involvement in aseptic processing. Personnel involved in microbial identification will require specialized training on required laboratory methods. Additional training on the management of the environmental data collected must be provided to personnel. Knowledge and understanding of applicable standard operating procedures is critical, especially those standard operating procedures relating to corrective measures that are taken when environmental conditions so dictate.

Understanding of regulatory compliance policies and each individual's responsibilities with respect to good manufacturing practices (GMPs) should be an integral part of the training program as well as training in conducting investigations and in analyzing data.

The major source of microbial contamination of controlled environments is the personnel. Contamination can occur from the spreading of microorganisms by individuals, particularly those with active infections. Only healthy individuals should be permitted access to controlled environments.

These facts underscore the importance of good personal hygiene and a careful attention to detail in the aseptic gowning procedure used by personnel entering the controlled environment. Once these employees are properly gowned—including complete facial coverage—they must be careful to maintain the integrity of their gloves and suits at all times. Since the major threat of contamination of product being aseptically processed comes from the operating personnel, the control of microbial contamination associated with these personnel is one of the most important elements of the environmental control program.

The importance of thorough training of personnel working in controlled environments, including aseptic techniques, cannot be overemphasized. The environmental monitoring program, by itself, will not be able to detect all events in aseptic processing that could compromise the microbiological quality of the environment. Therefore, periodic media-fill or process simulation studies to revalidate the process are necessary to assure that the appropriate operating controls and training are effectively maintained.

#### Critical Factors Involved in the Design and Implementation of a Microbiological Environmental Control Program

An environmental control program should be capable of detecting an adverse drift in microbiological conditions in a timely manner that would allow for meaningful and effective corrective actions. It is the responsibility of the manufacturer to develop, initiate, implement, and document such a microbial environmental monitoring program.

Although general recommendations for an environmental control program will be discussed, it is imperative that such a program be tailored to specific facilities and conditions. A general microbiological growth medium such as Soybean Casein Digest Medium should be suitable in most cases. This medium may be supplemented with additives to overcome or to minimize the effects of sanitizing agents, or of antibiotics if used or processed in these environments. The detection and quantitation of yeasts and molds should be considered.

General mycological media, such as Sabouraud's, Modified Sabouraud's, or Inhibitory Mold Agar are acceptable. Other media that have been validated for promoting the growth of fungi, such as Soybean-Casein Digest Agar, can be used. In general, testing for obligatory anaerobes is not performed routinely. However, should conditions or investigations warrant, such as the identification of these organisms in sterility testing facilities, more frequent testing is indicated. The ability of the selected media to detect and quantitate these anaerobes or microaerophilic microorganisms should be evaluated.

The selection of time and incubation temperatures is made once the appropriate media have been selected. Typically, incubation temperatures in the  $22.5 \pm 2.5^{\circ}\text{C}$  and  $32.5 \pm 2.5^{\circ}\text{C}$  ranges have been used with an incubation time of 72 and 48 hours, respectively. Sterilization processes used to prepare growth media for the environmental program should be

validated and, in addition, media should be examined for sterility and for growth promotion as indicated under [Sterility Tests](#) (71). In addition, for the Growth Promotion test, representative microflora isolated from the controlled environment or ATCC strain preparations of these isolates may also be used to test media. Media must be able to support growth when inoculated with less than 100 colony-forming units (cfu) of the challenge organisms.

An appropriate environmental control program should include identification and evaluation of sampling sites and validation of methods for microbiological sampling of the environment.

The methods used for identification of isolates should be verified using indicator microorganisms (see [Microbial Enumeration Tests](#) (61) and [Tests for Specified Microorganisms](#) (62)).

#### Establishment of Sampling Plan and Sites

During initial start-up or commissioning of a clean room or other controlled environment, specific locations for air and surface sampling should be determined. Consideration should be given to the proximity to the product and whether air and surfaces might be in contact with a product or sensitive surfaces of container-closure systems. Such areas should be considered critical areas requiring more monitoring than non-product-contact areas. In a parenteral vial filling operation, areas of operation would typically include the container-closure supply, paths of opened containers, and other inanimate objects (e.g., fomites) that personnel routinely handle.

The frequency of sampling will depend on the criticality of specified sites and the subsequent treatment received by the product after it has been aseptically processed. [Table 2](#) shows suggested frequencies of sampling in decreasing order of frequency of sampling and in relation to the criticality of the area of the controlled environment being sampled.

Table 2. Suggested Frequency of Sampling on the Basis of Criticality of Controlled Environment

Sampling Area	Frequency of Sampling
Class 100 or better room designations	Each operating shift
Supporting areas immediately adjacent to Class 100 (e.g., Class 10,000)	Each operating shift
Other support areas (Class 100,000)	Twice/week
Potential product/container contact areas	Twice/week
Other support areas to aseptic processing areas but non-product contact (Class 100,000 or lower)	Once/week

As manual interventions during operation increase, and as the potential for personnel contact with the product increases, the relative importance of an environmental monitoring program increases. Environmental monitoring is more critical for products that are aseptically processed than for products that are processed and then terminally sterilized. The determination and quantitation of microorganisms resistant to the subsequent sterilization treatment is more critical than the microbiological environmental monitoring of the surrounding manufacturing environments. If the terminal sterilization cycle is not based on the overkill cycle concept but on the bioburden prior to sterilization, the value of the bioburden program is critical.

The sampling plans should be dynamic with monitoring frequencies and sample plan locations adjusted based on trending performance. It is appropriate to increase or decrease sampling based on this performance.

#### Establishment of Microbiological Alert and Action Levels in Controlled Environments

The principles and concepts of statistical process control are useful in establishing Alert and Action levels and in reacting to trends.

An Alert level in microbiological environmental monitoring is that level of microorganisms that shows a potential drift from normal operating conditions. Exceeding the Alert level is not necessarily grounds for definitive corrective action, but it should at least prompt a documented follow-up investigation that could include sampling plan modifications.

An Action level in microbiological environmental monitoring is that level of microorganisms that when exceeded requires immediate follow-up and, if necessary, corrective action.

Alert levels are usually based upon historical information gained from the routine operation of the process in a specific controlled environment.

In a new facility, these levels are generally based on prior experience from similar facilities and processes; and at least several weeks of data on microbial environmental levels should be evaluated to establish a baseline.

These levels are usually re-examined for appropriateness at an established frequency. When the historical data demonstrate improved conditions, these levels can be re-examined and changed to reflect the conditions. Trends that show a deterioration of the environmental quality require attention in determining the assignable cause and in instituting a corrective action plan to bring the conditions back to the expected ranges. However, an investigation should be implemented and an evaluation of the potential impact this has on a product should be made.

## Microbial Considerations and Action Levels for Controlled Environments

Classification of clean rooms and other controlled environments is based on Federal Standard 209E based on total particulate counts for these environments. The pharmaceutical and medical devices industries have generally adopted the classification of Class 100, Class 10,000, and Class 100,000, especially in terms of construction specifications for the facilities.

Although there is no direct relationship established between the 209E controlled environment classes and microbial levels, the pharmaceutical industry has been using microbial levels corresponding to these classes for a number of years; and these levels have been those used for evaluation of current GMP compliance.<sup>2</sup> These levels have been shown to be readily achievable with the current technology for controlled environments. There have been reports and concerns about differences in these values obtained using different sampling

systems, media variability, and incubation temperatures. It should be recognized that, although no system is absolute, it can help in detecting changes, and thus trends, in environmental quality. The values shown in [Tables 3, 4, and 5](#) represent individual test results and are suggested only as guides. Each manufacturer's data must be evaluated as part of an overall monitoring program.

Table 3. Air Cleanliness Guidelines in Colony-Forming Units (cfu) in Controlled Environments (Using a Slit-to-Agar Sampler or Equivalent)

Class <sup>*</sup>		cfu per cubic meter of air <sup>**</sup>	cfu per cubic feet of air
SI	U.S. Customary		
M3.5	100	Less than 3	Less than 0.1
M5.5	10,000	Less than 20	Less than 0.5
M6.5	100,000	Less than 100	Less than 2.5

\* As defined in Federal Standard 209E, September 1992.

\*\* A sufficient volume of air should be sampled to detect excursions above the limits specified.

Table 4. Surface Cleanliness Guidelines of Equipment and Facilities in cfu in Controlled Environments

Class		cfu per Contact Plate <sup>*</sup>	
SI	U.S. Customary		
M3.5	100	3 (including floor)	
M5.5	10,000	5	
		10 (floor)	

\* Contact plate areas vary from 24 to 30 cm<sup>2</sup>. When swabbing is used in sampling, the area covered should be greater than or equal to 24 cm<sup>2</sup> but no larger than 30 cm<sup>2</sup>.

## Methodology and Instrumentation for Quantitation of Viable Airborne Microorganisms

It is generally accepted by scientists that airborne microorganisms in controlled environments can influence the microbiological quality of the intermediate or final products manufactured in these areas. Also, it generally is accepted that estimation of the airborne microorganisms can be affected by instruments and procedures used to perform these assays. Therefore, where alternative methods or equipment is used, the general equivalence of the results obtained should be ascertained. Advances in technology in the future are expected to bring innovations that would offer greater precision and sensitivity than the current available methodology and may justify a change in the absolute numbers of organisms that are detected.

Today, the most commonly used samplers in the U.S. pharmaceutical and medical device industry are the impaction and centrifugal samplers. A number of commercially available samplers are listed for informational purposes. The selection, appropriateness, and adequacy of using any particular sampler is the responsibility of the user.

**Slit-to-Agar Air Sampler (STA)**— This sampler is the instrument upon which the microbial guidelines given in [Table 3](#) for the various controlled environments are based. The unit is powered by an attached source of controllable vacuum. The air intake is obtained through a standardized slit below which is placed a slowly revolving Petri dish containing a nutrient agar. Particles in the air that have sufficient mass impact on the agar surface and viable organisms are allowed to grow out. A remote air intake is often used to minimize disturbance of the laminar flow field.

**Sieve Impactor**— The apparatus consists of a container designed to accommodate a Petri dish containing a nutrient agar. The cover of the unit is perforated, with the perforations of a predetermined size. A vacuum pump draws a known volume of air through the cover, and the particles in the air containing microorganisms impact on the agar medium in the Petri dish. Some samplers are available with a cascaded series of containers containing perforations of decreasing size. These units allow for the determination of the distribution of the size ranges of particulates containing viable microorganisms, based on which size perforations admit the particles onto the agar plates.

**Centrifugal Sampler**— The unit consists of a propeller or turbine that pulls a known volume of air into the unit and then propels the air outward to impact on a tangentially placed nutrient agar strip set on a flexible plastic base.

**Sterilizable Microbiological Atrium**— The unit is a variant of the single-stage sieve impactor. The unit's cover contains uniformly spaced orifices approximately 0.25 inch in size. The base of the unit accommodates one Petri dish containing a nutrient agar. A vacuum pump controls the movement of air through the unit, and a multiple-unit control center as well as a remote sampling probe are available.

**Surface Air System Sampler**— This integrated unit consists of an entry section that accommodates an agar contact plate. Immediately behind the contact plate is a motor and turbine that pulls air through the unit's perforated cover over the agar contact plate and beyond the motor, where it is exhausted. Multiple mounted assemblies are also available.

**Gelatin Filter Sampler**— The unit consists of a vacuum pump with an extension hose terminating in a filter holder that can be located remotely in the critical space. The filter consists of random fibers of gelatin capable of retaining airborne microorganisms. After a specified exposure time, the filter is aseptically removed and dissolved in an appropriate diluent and then plated on an appropriate agar medium to estimate its microbial content.

**Settling Plates**— This method is still widely used as a simple and inexpensive way to qualitatively assess the environments over prolonged exposure times. The exposure of open agar-filled Petri dishes, or settling plates, is not to be used for quantitative estimations of the microbial contamination levels of critical environments.

One of the major limitations of mechanical air samplers is the limitation in sample size of air being sampled. Where the microbial level in the air of a controlled environment is expected to contain not more than three cfu per cubic meter, several cubic meters of air should be tested if results are to be assigned a reasonable level of precision and accuracy. Often this is not practical. To show that microbial counts present in the environment are not increasing over time, it might be necessary to extend the time of sampling to determine if the time of sampling is a limiting factor or not. Typically, slit-to-agar samplers have an 80-liter-per-minute sampling capacity (the capacity of the surface air system is somewhat higher). If one cubic meter of air is tested, then it would require an exposure time of 15 minutes. It may be necessary to use sampling times in excess of 15 minutes to obtain a representative environmental sample. Although there are samplers reported to be capable of very high sampling volume rates, consideration in these situations should be given to the potential for disruption of the airflow patterns in any critical area or to the creation of a turbulence that could increase the probability of contamination.

For centrifugal air samplers, a number of earlier studies showed that the samples demonstrated a selectivity for larger particles. The use of this type of sampler may have resulted in higher airborne counts than the other types of air samplers because of that inherent selectivity.

When selecting a centrifugal sampler, the effect of the sampler on the linearity of the airflow in the controlled zone where it is placed for sampling should be taken into consideration. Regardless of the type of sampler used, the use of a remote probe requires determining that the extra tubing does not have an adverse effect on the viable airborne count. This effect should either be eliminated or, if this is not possible, a correction factor should be introduced in the reporting of results.

#### Methodology and Equipment for Sampling of Surfaces for Quantitation of Viable Microbial Contaminants in Controlled Environments

Another component of the microbial environmental control program in controlled environments is surface sampling of equipment, facilities, and personnel gear used in these environments. The standardization of surface sampling methods and procedures has not been as widely addressed in the pharmaceutical industry as the standardization of air sampling procedures.<sup>3</sup> To minimize disruptions to critical operations, surface sampling is performed at the conclusion of operations. Surface sampling may be accomplished by the use of contact plates or by the swabbing method. Surface monitoring is generally performed on areas that come in contact with the product and on areas adjacent to those contact areas.

Contact plates filled with nutrient agar are used when sampling regular or flat surfaces and are directly incubated at the appropriate time for a given incubation temperature for quantitation of viable counts. Specialized agar can be used for specific quantitation of fungi, spores, etc.

The swabbing method may be used for sampling of irregular surfaces, especially for equipment. Swabbing is used to supplement contact plates for regular surfaces. The swab is then placed in an appropriate diluent and the estimate of microbial count is done by plating of an appropriate aliquot on or in specified nutrient agar. The area to be swabbed is defined using a sterile template of appropriate size. In general, it is in the range of 24 to 30 cm<sup>2</sup>. The microbial estimates are reported per contact plate or per swab.

#### Culture Media and Diluents Used for Sampling or Quantitation of Microorganisms

The type of medium, liquid or solid, that is used for sampling or quantitation of microorganisms in controlled environments will depend on the procedure and equipment used. A commonly used all-purpose medium is Soybean-Casein Digest Agar when a solid medium is needed. Other media, liquid or solid, are listed below.

Liquid Media <sup>a</sup>	Solid Media <sup>a</sup>
Tryptone saline	Soybean-casein digest agar
Peptone water	Nutrient agar
Buffered saline	Tryptone glucose extract agar
Buffered gelatin	Lecithin agar
Enriched buffered gelatin	Brain heart infusion agar
Brain heart infusion	Contact plate agar
Soybean-casein medium	

<sup>a</sup> Liquid and solid media are sterilized using a validated process.

These media are commercially available in dehydrated form. They are also available in ready-to-use form. When disinfectants or antibiotics are used in the controlled area, consideration should be given to using media with appropriate inactivating agents.

Alternative media to those listed can be used provided that they are validated for the purpose intended.

#### Identification of Microbial Isolates from the Environmental Control Program

The environmental control program includes an appropriate level of identification of the flora obtained from sampling. A knowledge of the normal flora in controlled environments aids in determining the usual microbial flora anticipated for the facility being monitored; evaluating the effectiveness of the cleaning and sanitization procedures, methods, and agents; and recovery methods. The information gathered by an identification program can also be useful in the investigation of the source of contamination, especially when the Action levels are exceeded.

Identification of isolates from critical areas and areas immediate to these critical areas should take precedence over identification of microorganisms from noncritical areas. Identification methods should be verified, and ready-to-use kits should be qualified for their intended purpose (see Critical Factors Involved in the Design and Implementation of Environmental Control Program).

#### Operational Evaluation of the Microbiological Status of Aseptically Filled Products in Clean Rooms and Other Controlled Environments

The controlled environment is monitored through an appropriate environmental monitoring program. To assure that minimal bioburden is achieved, additional information on the evaluation of the microbiological status of the controlled environment can be obtained by the use of media fills. An acceptable media fill shows that a successful simulated product run can be conducted on the manufacturing line at that point in time. However, other factors are important, such as appropriate construction of facilities, environmental monitoring and training of personnel.

When an aseptic process is developed and installed, it is generally necessary to qualify the microbiological status of the process by running at least three successful consecutive media fills. A media fill utilizes growth medium in lieu of products to detect the growth of microorganisms. Issues in the development of a media fill program that should be considered are the following: media-fill procedures, media selection, fill volume, incubation, time and temperature, inspection of filled units, documentation, interpretation of results, and possible corrective actions required.

Since a media fill is designed to simulate aseptic processing of a specified product, it is important that conditions during a normal product run are in effect during the media fill. This includes the full complement of personnel and all the processing steps and materials that constitute a normal production run. During the conduct of media fill, various predocumented interventions that are known to occur during actual product runs should be planned (e.g., changing filling needles, fixing component jams).

Alternatively, in order to add a safety margin, a combination of possible conditions can be used. Examples may include frequent start and stop sequences, unexpected repair of processing system, replacement of filters, etc. The qualification of an aseptic process need not be done for every product, but should be done for each processing line. Since the geometry of the container (size as well as opening of the container) and the speed of the line are factors that are variable in the use of an aseptic processing line, appropriate combination of these factors, preferably at the extremes, should be used in the qualification of the line. A rationale for products used should be documented.

The 1987 FDA Guideline on Sterile Drug Products Produced by Aseptic Processing indicates that media-fill runs be done to cover all production shifts for line/product/container combinations. This guideline should be considered not only for qualification media-fill runs, but also for periodic reevaluation or revalidation. Media fill programs should also simulate production practices over extended runs. This can be accomplished by doing media-fill runs at the end of production runs.

In general, an all-purpose, rich medium such as Soybean Casein Broth that has been checked for growth promotion with a battery of indicator organisms (see [Sterility Tests](#) (71)) at a level of below 100 cfu/unit, can be used. Isolates from the controlled environment where aseptic processing is to be conducted may also be used. Following the aseptic processing of the medium, the filled containers are incubated at  $22.5 \pm 2.5^{\circ}\text{C}$  or at  $32.5 \pm 2.5^{\circ}\text{C}$ . All media filled containers should be incubated for a minimum of 14 days. If two temperatures are used for incubation of media filled samples, then these filled containers should be incubated for at least 7 days at each temperature. Following incubation, the medium-filled containers should be inspected for growth. Media filled isolates are identified by genus and, when possible, by species in order to investigate the sources of contamination.

Critical issues in performing media fills are the number of fills to qualify an aseptic process, the number of units filled per media fill, the interpretation of results, and implementation of

Corrective actions. Historically, three media-fill runs during initial qualification or start-up of a facility are conducted to demonstrate consistency of the aseptic processing line. The minimum number of units to demonstrate a contamination rate of not more than 0.1%, which is the criterion for acceptance of a successful media-fill run, is at least 3,000. It should be emphasized that many firms in the United States and other countries are filling more than 3,000 units in a single media-fill run.<sup>4</sup> Pilot plant facilities used for preparing small clinical lots may use smaller media fills.

A number of international documents (i.e., ISO and EU-GMP) have also cited an expectation of zero positives out of 3,000 media filled units at the 95% confidence level. However, it is recognized that repeated media runs are required in order to confirm the statistical validity of the observed contamination rate for the process.

PDA Technical Monograph Number 17,<sup>4</sup> "A Survey of Current Sterile Manufacturing Practices," indicated that many manufacturers believe that their aseptic processes are capable of contamination rates below 0.1%.

Since the most critical source of contamination in the clean room is the personnel, visual documentation that can be helpful in correlating production activities to contamination events during media fills is encouraged. The widespread use of isolator systems for sterility testing has demonstrated that elimination of personnel does reduce contamination in aseptic handling.

#### An Overview of the Emerging Technologies for Advanced Aseptic Processing

Because of the strong correlation between human involvement and intervention and the potential for product contamination in aseptic processing, production systems in which personnel are removed from critical zones have been designed and implemented. Methods developed to reduce the likelihood of contamination include equipment automation, barriers, and isolator systems. Facilities that employ these advanced aseptic processing strategies are already in operation. In facilities where personnel have been completely excluded from the critical zone, the necessity for room classification based on particulate and environmental microbiological monitoring requirements may be significantly reduced.

The following are definitions of some of the systems currently in place to reduce the contamination rate in aseptic processing:

**Barriers**—In the context of aseptic processing systems, a barrier is a device that restricts contact between operators and the aseptic field enclosed within the barrier. These systems are used in hospital pharmacies, laboratories, and animal care facilities, as well as in aseptic filling. Barriers may not be sterilized and do not always have transfer systems that allow passage of materials into or out of the system without exposure to the surrounding environment. Barriers range from plastic curtains around the critical production zones to rigid enclosures found on modern aseptic-filling equipment. Barriers may also incorporate such elements as glove ports, half-suits, and rapid-transfer ports.

**Blow/Fill/Seal**—This type of system combines the blow-molding of container with the filling of product and a sealing operation in one piece of equipment. From a microbiological point of view, the sequence of forming the container, filling with sterile product, and formation and application of the seal are achieved aseptically in an uninterrupted operation with minimal exposure to the environment. These systems have been in existence for about 30 years and have demonstrated the capability of achieving contamination rates below 0.1%.

Contamination rates of 0.001% have been cited for blow/fill/seal systems when combined media-fill data are summarized and analyzed.

**Isolator**—This technology is used for a dual purpose. One is to protect the product from contamination from the environment, including personnel, during filling and closing, and the other is to protect personnel from deleterious or toxic products that are being manufactured.

Isolator technology is based on the principle of placing previously sterilized components (containers/products/closures) into a sterile environment. These components remain sterile during the whole processing operation, since no personnel or nonsterile components are brought into the isolator. The isolator barrier is an absolute barrier that does not allow for interchanges between the protected and unprotected environments. Isolators either may be physically sealed against the entry of external contamination or may be effectively sealed by the application of continuous overpressure. Manipulations of materials by personnel are done via use of gloves, half-suits, or full suits. All air entering the isolator passes through either an HEPA or UPLA filter, and exhaust air typically exits through an HEPA-grade filter. Peracetic acid and hydrogen peroxide vapor are commonly used for the surface sterilization of the isolator unit's internal environment. The sterilization of the interior of isolators and all contents are usually validated to a sterility assurance level of 10<sup>-6</sup>.

Equipment, components, and materials are introduced into the isolator through a number of different procedures: use of a double-door autoclave; continuous introduction of components via a conveyor belt passing through a sterilizing tunnel; use of a transfer container system through a docking system in the isolator enclosure. It is also necessary to monitor closely an isolator unit's integrity, calibration, and maintenance.

The requirements for controlled environments surrounding these newer technologies for aseptic processing depend on the type of technology used.

**Blow/Fill/Seal** equipment that restricts employee contact with the product may be placed in a controlled environment, especially if some form of employee intervention is possible during production.

Barrier systems will require some form of controlled environment. Because of the numerous barrier system types and applications, the requirements for the environment surrounding the barrier system will vary. The design and operating strategies for the environment around these systems will have to be developed by the manufacturers in a logical and rational fashion. Regardless of these strategies, the capability of the system to produce sterile products must be validated to operate in accordance with pre-established criteria.

In isolators, the air enters the isolator through integral filters of HEPA quality or better, and their interiors are sterilized typically to a sterility assurance level of 10<sup>-6</sup>; therefore, isolators contain sterile air, do not exchange air with the surrounding environment, and are free of human operators. However, it has been suggested that when the isolator is in a controlled environment, the potential for contaminated product is reduced in the event of a pinhole leak in the suit or glove.

The extent and scope of an environmental microbiological monitoring of these advanced systems for aseptic processing depends on the type of system used. Manufacturers should balance the frequency of environmental sampling systems that require human intervention with the benefit accrued by the results of that monitoring. Since barrier systems are designed to reduce human intervention to a minimum, remote sampling systems should be used in lieu of personnel intervention. In general, once the validation establishes the effectiveness of the barrier system, the frequency of sampling to monitor the microbiological status of the aseptic processing area could be reduced, as compared to the frequency of sampling of classical aseptic processing systems.

Isolator systems require relatively infrequent microbiological monitoring. Continuous total particulate monitoring can provide assurance that the air filtration system within the isolator is working properly. The methods for quantitative microbiological air sampling described in this chapter may not have sufficient sensitivity to test the environment inside an isolator. Experience with isolators indicates that under normal operations pinhole leaks or tears in gloves represent the major potential for microbiological contamination; therefore, frequent testing of the gloves for integrity and surface monitoring of the gloves is essential. Surface monitoring within the isolator may also be beneficial on an infrequent basis.

#### GLOSSARY

**Airborne Particulate Count** (also referred to as Total Particulate Count)—Particles detected are 0.5  $\mu\text{m}$  and larger. When a number of particles is specified, it is the maximum allowable number of particles per cubic meter of air (or per cubic foot of air).

**Airborne Viable Particulate Count** (also referred to as Total Airborne Aerobic Microbial Count)—When a number of microorganisms is specified, it is the maximum number of colony-forming units (cfu) per cubic meter of air (or per cubic foot of air) that is associated with a Cleanliness Class of controlled environment based on the Airborne Particulate Count.

**Aseptic Processing**—A mode of processing pharmaceutical and medical products that involves the separate sterilization of the product and of the package (containers/closures or packaging material for medical devices) and the transfer of the product into the container and its closure under microbiologic critically controlled conditions.

**Air Sampler**—Devices or equipment used to sample a measured amount of air in a specified time to quantitate the particulate or microbiological status of air in the controlled environment.

**Air Changes**—The frequency per unit of time (minutes, hours, etc.) that the air within a controlled environment is replaced. The air can be recirculated partially or totally replaced.

**Action Levels**—Microbiological levels in the controlled environment, specified in the standard operating procedures, which when exceeded should trigger an investigation and a corrective action based on the investigation.

Alert Levels—Microbial levels, specified in the standard operating procedures, which when exceeded should result in an investigation to ensure that the process is still within control. Alert levels are specific for a given facility and are established on the basis of a baseline developed under an environmental monitoring program. These Alert levels can be modified depending on the trend analysis done in the monitoring program. Alert levels are always lower than Action levels.

Bioburden—Total number of microorganisms detected in or on an article.

Clean Room—A room in which the concentration of airborne particles is controlled to meet a specified airborne particulate Cleanliness Class. In addition, the concentration of microorganisms in the environment is monitored; each Cleanliness Class defined is also assigned a microbial level for air, surface, and personnel gear.

Clean Zone—A defined space in which the concentration of airborne particles and microorganisms are controlled to meet specific Cleanliness Class levels.

Controlled Environment—Any area in an aseptic process system for which airborne particulate and microorganism levels are controlled to specific levels, appropriate to the activities conducted within that environment.

Commissioning of a Controlled Environment—Certification by engineering and quality control that the environment has been built according to the specifications of the desired cleanliness class and that, under conditions likely to be encountered under normal operating conditions (or worst-case conditions), it is capable of delivering an aseptic process. Commissioning includes media-fill runs and results of the environmental monitoring program.

Corrective Action—Actions to be performed that are in standard operating procedures and that are triggered when certain conditions are exceeded.

Environmental Isolates—Microorganisms that have been isolated from the environmental monitoring program.

Environmental Monitoring Program—Documented program, implemented through standard operating procedures, that describes in detail the procedures and methods used for monitoring particulates as well as microorganisms in controlled environments (air, surface, personnel gear). The program includes sampling sites, frequency of sampling, and investigative and corrective actions that should be followed if Alert or Action levels are exceeded. The methodology used for trend analysis is also described.

Equipment Layout—Graphical representation of an aseptic processing system that denotes the relationship between and among equipment and personnel. This layout is used in the Risk Assessment Analysis to determine sampling site and frequency of sampling based on potential for microbiological contamination of the product/container/closure system. Changes must be assessed by responsible managers, since unauthorized changes in the layout for equipment or personnel stations could result in increase in the potential for contamination of the product/container/closure system.

Federal Standard 209E—"Airborne Particulate Cleanliness Classes in Clean Rooms and Clean Zones" is a standard approved by the Commissioner, Federal Supply Services, General Service Administration, for the use of "All Federal Agencies." The Standard establishes classes of air cleanliness based on specified concentration of airborne particulates. These classes of air cleanliness have been developed, in general, for the electronic industry "super-clean" controlled environments. In the pharmaceutical industry, the Federal Standard 209E is used to specify the construction of controlled environment. Class 100, Class 10,000, and Class 100,000 are generally represented in an aseptic processing system. If the classification system is applied on the basis of particles equal to or greater than 0.5  $\mu\text{m}$ , these classes are now represented in the SI system by Class M3.5, M5.5, and M6.5, respectively.

Filter Integrity—Testing that ensures that a filter functional performance is satisfactory [e.g., diethyl phthalate (DOP) and bubble point test].

Material Flow—The flow of material and personnel entering controlled environments should follow a specified and documented pathway that has been chosen to reduce or minimize the potential for microbial contamination of the product/closure/container systems. Deviation from the prescribed flow could result in increase in potential for microbial contamination.

Material/personnel flow can be changed, but the consequences of the changes from a microbiological point of view should be assessed by responsible managers and must be authorized and documented.

Media Growth Promotion—Procedure that references Growth Promotion under [Sterility Tests](#) 71 to demonstrate that media used in the microbiological environmental monitoring program, or in media-fill runs, are capable of supporting growth of indicator microorganisms and of environmental isolates from samples obtained through the monitoring program or their corresponding ATCC strains.

Media Fill—Microbiological simulation of an aseptic process by the use of growth media processed in a manner similar to the processing of the product and with the same container/closure system being used.

Out-of-Specification Event—Temporary or continuous event when one or more of the requirements included in standard operating procedures for controlled environments are not fulfilled.

Product Contact Areas—Areas and surfaces in a controlled environment that are in direct contact with either products, containers, or closures and the microbiological status of which can result in potential microbial contamination of the product/container/closure system. Once identified, these areas should be tested more frequently than non-product-contact areas or surfaces.

Risk Assessment Analysis—Analysis of the identification of contamination potentials in controlled environments that establish priorities in terms of severity and frequency and that will develop methods and procedures that will eliminate, reduce, minimize, or mitigate their potential for microbial contamination of the product/container/closure system.

Sampling Plan—A documented plan that describes the procedures and methods for sampling a controlled environment; identifies the sampling sites, the sampling frequency, and number of samples; and describes the method of analysis and how to interpret the results.

Sampling Sites—Documented geographical location, within a controlled environment, where sampling for microbiological evaluation is taken. In general, sampling sites are selected because of their potential for product/container/closure contacts.

Standard Operating Procedures—Written procedures describing operations, testing, sampling, interpretation of results, and corrective actions that relate to the operations that are taking place in a controlled environment and auxiliary environments. Deviations from standard operating procedures should be noted and approved by responsible managers.

Sterile Field—In aseptic processing or in other controlled environments, it is the space at the level of or above open product containers, closures, or product itself, where the potential for microbial contamination is highest.

Sterility—Within the strictest definition of sterility, an article is deemed sterile when there is complete absence of viable microorganisms. Absolute sterility cannot be practically demonstrated without testing every article in a batch. Sterility is defined in probabilistic terms, where the likelihood of a contaminated article is acceptably remote.

Swabs—Devices provided that are used to sample irregular as well as regular surfaces for determination of microbial status. The swab, generally composed of a stick with an absorbent extremity, is moistened before sampling and used to sample a specified unit area of a surface. The swab is then rinsed in sterile saline or other suitable menstruum and the contents plated on nutrient agar plates to obtain an estimate of the viable microbial load on that surface.

Trend Analysis—Data from a routine microbial environmental monitoring program that can be related to time, shift, facility, etc. This information is periodically evaluated to establish the status or pattern of that program to ascertain whether it is under adequate control. A trend analysis is used to facilitate decision-making for requalification of a controlled environment or for maintenance and sanitization schedules.

1 Interaction Between Air Movements and the Dispersion of Contaminants: Clean Zones with Unidirectional Air Flow, *Journal of Parenteral Science and Technology*, 47(2), 1993.

2 NASA, 1967—*Microbiology of Clean Rooms*.

3 The Sixteenth Edition of Standard Methods for the Examination of Dairy Products (the American Health Association) provides a section on surface sampling.

4 A Parenteral Drug Association Survey (Technical Monograph 17) showed that out of 27 respondents, 50% were filling more than 3,000 units per run.

## 1117 MICROBIOLOGICAL BEST LABORATORY PRACTICES

### INTRODUCTION

Good laboratory practices in a microbiology laboratory consist of activities that depend on several principles: aseptic technique, control of media, control of test strains, control of equipment, diligent recording and evaluation of data, and training of the laboratory staff. Because of the known variability in microbiology data, reliability and reproducibility are dependent on the use of accepted methods and adherence to good laboratory practices.

### MEDIA PREPARATION AND QUALITY CONTROL

#### Media Preparation

Culture media are the basis for most microbiological tests. Safeguarding the quality of this media is therefore critical to the success of the microbiology laboratory. Media preparation, proper storage, and quality control testing can assure a consistent supply of high quality media.

It is important to choose the correct media or components in making media based on the use of accepted sources or references for formulas. The manufacturer's formula and instructions for preparation routinely accompany dehydrated media and ready-made media. Because different media types may have different preparation requirements (e.g., heating, additives, and pH adjustment), it is important to follow these instructions to ensure preparation of acceptable media quality. A certificate of analysis describing expiry dating and recommended storage conditions accompanies ready-made media, as well as the quality control organisms used in growth-promotion and selectivity testing of that media.

Water is the universal diluent for microbiological media. Purified Water is most often used for media preparation, but in certain cases the use of deionized or distilled water may be appropriate. The volume of the water used should be recorded.

Consistent preparation of media requires accurate weighing of dehydrated media or media constituents. A calibrated balance with the appropriate weight range for the ingredients should be used. Clean weighing containers and tools (such as spatulas) should be used to prevent foreign substances that may alter the composition of the finished media from entering the formulation. The weight of the components should be recorded.

Dehydrated media should be thoroughly dissolved in water prior to dispensing and sterilization. If heating is necessary to help dissolve media, care should be taken not to overheat media as all culture media, to a greater or lesser extent, are heat-sensitive. Equipment used in the preparation of media should be appropriate to allow for controlled heating, constant agitation, and mixing of the media. Darkening of media (Maillard-type reaction or nonenzymatic browning) is a general indication of overheating. When adding required supplements to media, adequate mixing of the medium after adding the supplement should be performed.

Preparation of media in poorly cleaned glassware can allow inhibitory substances to enter the media. Inhibitory substances can come from detergent residue after cleaning glassware or from prior materials used in the glassware. Be sure that the cleaning process removes debris and foreign matter, and that the detergent is thoroughly rinsed out with Purified Water.

See [Cleaning Glass Apparatus](#) (1051) for additional guidance.

Sterilization of media should be performed within the parameters provided by the manufacturer or validated by the user. Commercially prepared media should provide documentation of the sterilization method that was used. Ideally the manufacturer should provide the sterility assurance level (SAL) of the media against a recognized biological indicator. Autoclaving by moist heat is the preferred sterilization technique, except in instances when boiling is required in order to avoid deterioration of heat-labile components of the media. Sterilization by filtration may also be appropriate for some formulations.

The effects of the sterilization method and conditions on the media should be validated by sterility and growth-promotion testing of the media. In addition, if sterilized by moist heat, the autoclave cycle should be validated to ensure proper heat distribution for selected loads and volumes. Typically, manufacturers recommend using an autoclave cycle of 121° for 15 minutes using a validated autoclave. These conditions apply to time at temperature of the media. As the load configuration of the autoclave will influence the rate of heating, longer cycles may be required for larger loads. However, the sterilization time will be dependent on the media volume and autoclave load. Sterilization cycles in which the autoclave is slow to come up to temperature may result in overheating of the media. Therefore, care must be taken to validate a sterilization cycle to deliver the minimum SAL required, balancing the need for a sterile media against the tendency of the media to degrade under excessive heating. Storage of the media in the autoclave after the liquid cycle is completed is not recommended after cooling, as it may damage the media. Improper heating or sterilizing conditions—for commercially prepared or internally prepared media—may result in a difference in color change, loss of clarity, altered gel strength, or pH drift from the manufacturer's recommended range.

The pH of each batch of medium should be confirmed after it has cooled to room temperature (25°) by aseptically withdrawing a sample for testing. A flat pH probe is recommended for agar surfaces, and an immersion probe is recommended for liquids. The pH of media should be in a range of  $\pm 0.2$  of the value indicated by the manufacturer, unless a wider range is acceptable by the validated method.

Prepared media should be checked by appropriate inspection of plates and tubes for:

- Cracked containers or lids
  - Unequal filling of containers
  - Dehydration resulting in cracks or dimpled surfaces on solid medium
    - Hemolysis
    - Excessive darkening or color change
    - Crystal formation from possible freezing
      - Excessive number of bubbles
      - Microbial contamination
    - Status of redox indicators (if appropriate)
  - Lot number and expiry date checked and recorded
    - Sterility of the media
- Media Storage

It is prudent to consider how the manufacturer or supplier transports and stores media prior to distribution to the end user. Manufacturers of media should use transport and storage conditions that minimize the loss of moisture, control the temperature, and provide mechanical protection to the prepared media.

Media should be labeled properly with batch or lot numbers, preparation and expiration dates, and media identification. Media should be stored according to the manufacturer's instructions. Media prepared in-house should be stored under validated conditions. Do not store agar at or below 0°, as freezing could damage the gel structure. Protect stored media from exposure to light and excessive temperature. Before prolonged storage, agar plates should be placed into a sealed package or container to retard moisture loss.

Remelting of an original container of solid media should be performed only once to avoid media whose quality is compromised by overheating or potential contamination. It is recommended that remelting be performed in a heated water bath or by using free-flowing steam. The use of microwave ovens and heating plates is common, but care should be taken to avoid damaging media by overheating and to avoid the potential injury to laboratory personnel from glass breakage and burns. The molten agar medium should be held in a monitored water bath at a temperature of 45° to 50° for not more than 8 hours. Caution should be taken when pouring the media from a container immersed in a water bath to prevent

water from the bath commingling with the poured sterile media. Wiping the exterior of the container dry prior to pouring may be advisable.

Disposal of used cultured media (as well as expired media) should follow local biological hazard safety procedures.

#### Quality Control Testing

While growth media can be prepared in a laboratory from individual components, many laboratories, for their ease-of-use, use dehydrated media or purchase commercially prepared media in plates or glass containers. Manufacturers of media attempt to standardize raw materials from biological sources, but must constantly deal with unavoidable differences in raw materials obtained from natural sources, and therefore, lot-to-lot variability of media must be considered. The performance of media prepared in a laboratory or by a manufacturer is highly dependent on preparation. Improper media preparation can cause unsatisfactory conditions for microbial growth or recovery and unreliable results.

Quality control tests should be performed on all prepared media. Tests routinely performed on in-house prepared media are pH, growth promotion, and periodic stability checks to confirm the expiry dating.

When in-house prepared microbiological media are properly prepared and sterilized using a validated method, the growth-promotion testing may be limited to each incoming lot of dehydrated media, unless otherwise instructed by the relevant compendial method. If the media preparation was not validated, then every batch of media would be subjected to growth-promotion testing. Test organisms may be selected from the appropriate compendial test chapter, based on the manufacturer's recommendation for a particular medium, or may include representative environmental isolates.

Expiration dates on media should have supporting growth-promotion testing to indicate that the performance of the media still meets acceptance criteria up to and including the expiration date. The length of shelf life of a batch of media will depend on the stability of the ingredients and formulation under specified conditions, as well as the type of container and closure.

When a batch of media does not meet the requirements of growth-promotion testing, an investigation should be initiated to identify the cause. This investigation should include a corrective action plan to prevent the recurrence of the problem. Any nonconforming lot should not be used if an assignable cause or corrective resolution relative to nongrowth support is undetermined.

Some reagents are used for diagnostic purposes to help support identification of microbial organisms, e.g., Gram stain and oxidase test reagents. These may have attributes that can be quality control tested similar to microbiological media. Select the correct quality control standard microorganisms, following the manufacturer's instructions, and perform the testing prior to unknown sample diagnostic testing.

Special care should be taken with media that is used in environmental monitoring studies. Media used for environmental monitoring of critical areas should preferably be double-wrapped and terminally sterilized. If terminal sterilization is not performed, media should be subjected to pre-incubation and 100% inspection prior to use within a critical area. This will prevent extraneous contamination from being carried into controlled environments and will prevent false-positive results. A raised agar level for surface contact plates should be verified.

#### MAINTENANCE OF MICROBIOLOGICAL CULTURES

Biological specimens can be the most delicate standards to handle because their viability and characteristics are dependent on adequate handling and storage. Standardizing the handling and storage of cultures by the user laboratory should be done in a way that will minimize the opportunity for contamination or alteration of growth characteristics. The careful and consistent treatment of stock cultures is critically important to the consistency of microbiological test results. Cultures for use in compendial tests should be acquired from a national culture collection. They can be acquired frozen, freeze-dried, on slants, or in ready-to-use forms. Confirmation of the purity of the culture and the identity of the culture should be performed prior to its use in quality control testing. Ready-to-use cultures may require confirmation of purity, identity, and inoculum size. This confirmation of identity for commonly used laboratory strains should ideally be done at the level of genotypic analysis (i.e., DNA fingerprinting, 16S rRNA gene sequencing, or PCR analysis using suitably validated probes).

Preparation and resuscitation of cultures should follow the instructions of the supplier or a validated, established method. The "Seed-Lot" technique is recommended for storage of stock cultures.

The original sample from the national culture collection is resuscitated and grown in an appropriate medium. Aliquots of this stock culture (the first transfer or passage) are suspended in a cryoprotective medium, transferred to vials, and frozen at  $-30^{\circ}$  or below, until use. If stored at  $-70^{\circ}$ , or in lyophilized form, strains may be kept indefinitely. These frozen stocks should then be used to inoculate monthly or weekly working cultures. Once opened, do not refreeze unused cell suspensions after culturing a working suspension. The unused portion should be discarded to minimize the risk of loss of viability and contamination of the stock.

The number of transfers of working control cultures should be tracked to prevent excessive subculturing that increases the risk of phenotypic alteration. One passage is defined as the transfer of organisms from a viable culture to a fresh medium with growth of the microorganisms. Any form of subculturing is considered to be a transfer/passage.

#### MAINTENANCE OF LABORATORY EQUIPMENT

Most equipment (incubators, water baths, and autoclaves) is subject to standard validation practices of incoming qualification, operational qualification, and performance qualification. Additionally, periodic calibration (generally annually) is commonly required. New equipment, critical to the operation of the laboratory, should be qualified according to a protocol approved by the quality assurance unit (QAU).

Instruments (pH meters and spectrophotometers) used in a microbiology laboratory should be calibrated on a regular schedule and tested to verify performance on a routine basis. The frequency of calibration and performance verification will vary based on the type of instrument and the importance of that equipment to the generation of data in the laboratory.

#### LABORATORY LAYOUT AND OPERATIONS

Laboratory layout and design should carefully consider the requirements of good microbiological practices and laboratory safety. It is essential that cross-contamination of microbial cultures be minimized to the greatest extent possible, and it is also important that microbiological samples be handled in an environment that makes contamination highly unlikely.

In general, a laboratory should be divided into clean or aseptic areas and live culture areas. Areas in which environmental or sterile product samples are handled and incubated should be maintained completely free of live cultures, if possible. If complete separation of live and clean culture zones cannot be accomplished, then other barriers and aseptic practices should be employed to reduce the likelihood of accidental contamination. These barriers include protective clothing, sanitization and disinfection procedures, and biological safety cabinets designated for clean or aseptic operations only. Procedures for handling spills or mishaps with live cultures should be in place, and all relevant technical personnel should be trained regarding these methods.

Some samples will demonstrate microbial growth and require further laboratory analysis to identify the contaminants. When growth is detected, the sample should be taken from the clean section of the laboratory to the live culture section without undue delay. Subculturing, staining, microbial identification, or other investigational operations should be undertaken in the live culture section of the laboratory. If possible, any sample found to contain growing colonies should not be opened in the clean zone of the laboratory. Careful segregation of contaminated samples and materials will reduce false-positive results.

Staff engaged in sampling activities should not enter or work in the live culture handling section of a laboratory unless special precautions are taken, including wearing protective clothing and gloves, and careful sanitization of hands upon exiting. Ideally, staff assigned to sampling activities, particularly those in support of aseptic processing, should not work in the vicinity of live culture laboratory operations. Also, all microbiological samples should be taken using aseptic techniques, including those taken in support of nonsterile products. If possible, all microbiological samples should be taken under full aseptic conditions in specialized sampling areas.

It is important to consider that microbial contamination of samples, which leads to false-positive results, is always possible unless careful aseptic precautions are taken. Facilities should be designed so that raw material and excipient sampling can be done under controlled conditions, including proper gowning and sterilized sampling equipment. It may not always be possible to sample utility systems, such as water systems, under full aseptic conditions; however, it should be noted that when samples are not taken aseptically, their

reliability is inevitably compromised.

Environmental sampling methods should require minimal aseptic handling in loading and unloading sampling instruments. Whenever possible, sampling equipment should be loaded with its microbiological recovery media in the environment that is to be sampled.

All testing in laboratories used for critical testing procedures, such as sterility testing of final dosage forms, bulk product, seed cultures for biological production, or cell cultures used in biological production, should be performed under controlled conditions. Isolator technology is also appropriate for critical, sterile microbiological testing. Isolators have been shown to have lower levels of environmental contamination than manned clean rooms, and therefore, are generally less likely to produce false-positive results. Proper validation of isolators is critical both to ensure environmental integrity and to prevent the possibility of false-negative results as a result of chemical disinfection of materials brought into or used within isolators (see [Sterility Testing—Validation of Isolator Systems \(1208\)](#)).

#### TRAINING OF PERSONNEL

Each person engaged in all phases of pharmaceutical manufacture should have the education, training, and experience to do his or her job. The demands of microbiological testing require that the core educational background of the staff, supervisors, and managers be in microbiology or a closely related biological science. They should be assigned responsibilities in keeping with their level of skill and experience.

A coherent system of operating procedures is necessary to run the microbiology laboratory. These procedures serve two purposes in a training program. Firstly, these SOPs describe the methodology that the microbiologist will follow to obtain accurate and reproducible results, and so serve as the basis for training. Secondly, by tracking the procedures in which a particular microbiologist has demonstrated proficiency, the procedure number or title also serves to identify what training the microbiologist has received specific to his or her job function.

Training curricula should be established for each laboratory staff member specific for his or her job function. They should not independently conduct a microbial test until they are qualified to run the test. Training records should be current, documenting the microbiologist's training in the proper revision to the particular SOP.

Periodic performance assessment is a wise investment in data quality. This performance testing should provide evidence of competency in core activities of the microbiology laboratory such as hygiene, plating, aseptic technique, documentation, and others as suggested by the microbiologist's job function.

Microbiologists with supervisory or managerial responsibilities should have appropriate education and in-house training in supervisory skills, laboratory safety, scheduling, laboratory investigations, technical report writing, relevant SOPs, and other critical aspects of the company's processes as suggested in their role of directing a laboratory function.

#### DOCUMENTATION

Documentation should be sufficient to demonstrate that the testing was performed in a laboratory and by methods that were under control. This includes, but is not limited to, documentation of the following:

- Microbiologist training and verification of proficiency
- Equipment validation, calibration, and maintenance
- Equipment performance during test (e.g., 24-hour/7-day chart recorders)
- Media preparation, sterility checks, and growth-promotion and selectivity capabilities
  - Media inventory and control testing
- Critical components of test conducted as specified by a procedure
  - Data and calculations verified
- Reports reviewed by QAU or a qualified responsible manager
  - Investigation of data deviations (if needed)

#### MAINTENANCE OF LABORATORY RECORDS

Proper recording of data and studies is critical to the success of the microbiology laboratory. The over-riding principle is that the test should be performed as written in the SOP, the SOP should be written to reflect how the test is actually performed, and the laboratory notebook should provide a record of all critical details needed to confirm the integrity of the data. At a minimum, the laboratory write-up should include the following:

- Date
- Material tested
- Microbiologist's name
- Procedure number
- Document test results
- Deviations (if any)
- Documented parameters (equipment used, microbial stock cultures used, media lots used)
- Management/Second review signature

Every critical piece of equipment should be noted in the write-up, and all should be on a calibration schedule documented by SOP and maintenance records. Where appropriate, logbooks or forms should be available and supportive of the laboratory notebook records. Equipment temperatures (waterbaths, incubators, autoclaves) should be recorded and traceable.

The governing SOP and revision should be clearly noted in the write-up. Changes in the data should be crossed off with a single line and initialed. Original data should not be erased or covered over.

Test results should include the original plate counts, allowing a reviewer to recreate the calculations used to derive the final test results. Methods for data analysis should be detailed in cited SOPs.

All laboratory records should be archived and protected against catastrophic loss. A formal record retention and retrieval program should be in place.

#### INTERPRETATION OF ASSAY RESULTS

Analytical microbiological assay results can be difficult to interpret for several important reasons: (1) Microorganisms are both ubiquitous in nature and common environmental contaminants, particularly organisms associated with humans predominate in many types of microbiological analysis; (2) The analyst has the potential to introduce contaminating organisms during sample handling or processing in the laboratory; (3) Microorganisms may not be homogeneously distributed within a sample or an environment; and (4) Microbiological assays are subject to considerable variability of outcome. Therefore, minor differences from an expected outcome may not be significant.

Because of these characteristics of microbiological analysis, laboratory studies should be conducted with the utmost care to avoid exogenous contamination as previously discussed in this chapter. Equally important, results must be interpreted from a broad microbiological perspective considering not only the nature of the putative contaminant, but the likelihood of that organism(s) surviving in the pharmaceutical ingredient, excipient, or environment under test. In addition, the growth characteristics of the microorganism should be considered (especially in questions of the growth of filamentous fungi in liquid media).

When results are observed that do not conform to a compendial monograph or another established quantitative target, an investigation into the finding is required. There are generally two distinct reasons for the observation of microbial contamination that does not comply with a target or requirement: There may be either a laboratory error or laboratory environmental conditions that produced an invalid result, or the product contains a level of contamination or specific types of contaminants outside established levels or limits. In either

case, laboratory management and, in most cases, general management should be notified immediately.

A full and comprehensive evaluation of the situation surrounding the result should be undertaken. All microbiological conditions or factors that could bring about the observed condition should be fully considered, including the magnitude of the excursion compared to established limits or levels. It is critical to know if the finding is statistically significant in light of assay variability.

The laboratory environment, the protective conditions in place for sampling, historical findings concerning the material under test, and the nature of the material, particularly with regard to microbial survival or proliferation in contact with the material, should be considered in the investigation. In addition, interviews with the laboratory analyst(s) may provide information regarding the actual conduct of the assay that can be valuable in determining the reliability of the result and in determining an appropriate course of action. If laboratory operations are identified as the cause of the nonconforming test outcome, then a corrective action plan should be developed to address the problem(s). Following the approval and implementation of the corrective action plan, the situation should be carefully monitored and the adequacy of the corrective action determined.

If assay results are invalidated based upon the discovery of an attributable error, this action must be documented. Laboratories also should have approved procedures for confirmatory testing (retesting), and if necessary, resampling where specific regulatory or compendial guidance do not govern the conduct of an assay investigation.

#### 1118 MONITORING DEVICES—TIME, TEMPERATURE, AND HUMIDITY

This chapter provides background on the science and technology of temperature and humidity monitoring. It describes the available technologies and their performance characteristics, and it provides recommendations for verification and validation of performance. The shelf life of a drug is a function of the temperature and humidity conditions under which it is stored and transported as well as the chemical and physical properties of the drug substance and preparation. For this reason, the ability to monitor those conditions is important in the shipping and storage of temperature- and humidity sensitive preparations. Historic geographic and seasonal trends may be used as a planning tool in selecting among the types of temperature and humidity monitoring devices. Meteorological forecasts are available for any pertinent location.

#### TEMPERATURE MEASUREMENT TECHNOLOGIES

The devices described in this section are those most commonly used to monitor temperature in the storage and distribution of drugs in North America. The measurement of temperature at extremes, such as close to absolute zero or above those reasonably expected to be experienced by drugs, is not addressed.

**Alcohol or Mercury Thermometers**— These devices are based on the change in volume of a liquid as a function of temperature. Mercury thermometers are typically used in the ranges from 0° to 50° with a precision of about 0.1°. [note—Some local regulations apply to mercury-based thermometers. Alcohol thermometers may have a precision as good as 0.01°, but they must be quite large to measure temperatures in ranges of more than a few degrees. Both types of thermometers may be designed to indicate the maximum and minimum temperatures measured. See [Thermometers \(21\)](#).]

**Chemical Device**— This is a device based on a phase change or chemical reaction that occurs as a function of temperature. Examples include liquid crystals, waxes, and lacquers that change phase, and thereby their appearance, as a function of temperature. Such materials represent the least expensive form of temperature measurement, but they may be difficult to interpret.

Other types of chemical sensors include systems in which a reaction rate or diffusion process is used to deduce a temperature equivalent integrated over time rather than the temperature at a specific moment in time such as a spike or critical threshold, for which a separate device may be preferred. Thus, chemical sensors provide a measure of accumulated heat rather than instantaneous temperature. It should be noted that these devices are generally irreversible; once a color change or diffusion process has taken place, exposure to low temperatures will not restore the device to its original state. Accuracy and precision vary widely among different types, to differentiate often limited by their ability or their ability to visually interpret diffusion distances.

**Infrared Device**— This is a device based on measuring the IR radiation from the article whose temperature is being determined; the IR radiation varies as a function of the object's temperature. The advantage of the device is that the article may be at some distance from the IR sensor. However, IR devices are expensive compared to other temperature sensors.

**Resistance Temperature Detector (RTD)**— This is a device based on the change in electrical resistance of a material as a function of temperature. Precision and accuracy depend on the quality of the electronics used to measure the resistance. Therefore, although RTDs are among the most stable and accurate temperature sensors, their accuracy may change with the age and temperature of the device as its electronic components are affected. A particular type of RTD uses platinum or platinum alloy wire as the sensor. These are referred to as platinum resistance temperature detectors (PRT or PRTD).

**Solid State Device**— This is a device based on the effect of temperature on either an integrated circuit (see Thermistor below) or a micromechanical or microelectrical system. These devices can attain the highest precision available and also have the advantage of producing a digital output. Their accuracy is typically limited by the accuracy of the calibrating system employed.

**Thermistor**— This is a semiconductor device whose resistance varies with temperature. Thermistors are able to detect very small changes in temperature. They are accurate over a broad range of temperatures.

**Thermocouple**— This is a device based on the change in the junction potential of two dissimilar metals as a function of temperature. Many metal pairs may be used, with each pair providing a unique range, accuracy, and precision. Precision and accuracy depend on the quality of the electronics used to measure the voltage and the type of temperature reference used. Accuracy may be a function of temperature reference used. Thermocouples have relatively poor stability and low sensitivity, but are simple and cover a wide temperature range.

**Thermomechanical Device**— This is a device based on the change in volume of a solid material as a function of temperature. For example, a mechanical spring, which expands or contracts as a function of temperature, thus opening and closing an electrical circuit or moving a chart pen, is such a device. Precision may be as good as 0.05°, but in practice it is rarely better than 0.5°. Accuracy is often in the range of ±1.0°, but it may change with the age and temperature of the device.

#### TIME-TEMPERATURE INTEGRATORS

Time-temperature integrators, commonly referred to as TTIs, change color or physical appearance as a result of exposure to a temperature above a specific threshold for a specific time duration, and thus accumulate heat. TTIs are typically single use, disposable devices that react irreversibly. Once the color changes, it will not revert to the original one even if the temperature returns to the acceptable, normal range. The four basic types of chemical-based TTIs are described below.

**Table 1** lists the four types of chemical TTIs presently in use. The closer the activation energy of the TTI's color change to the activation energy of the degradation process of the drug being monitored, the more accurately the TTI will reflect the status of the drug. In actual practice, the activation energy for degradation of a particular drug is not known precisely enough to enable selection of a particular type of TTI. The range of possible activation energies of a TTI is given in the table to provide a sense of the flexibility of that particular technology. A TTI with a range of possible activation energies can be configured to cover a wider range of time and temperature thresholds.

Table 1. Characteristics of TTI Technologies

	Activation		

Type	Storage	Energy (kcal/mol)	Indication	Placement	Activation
Chemical-Physical	Controlled room temperature	13-80	Readable message or image	Primary label or primary package	Placement of activator tape over indicator
Polymerization	-44°	21 or 37	Readable message or image	Primary label or primary package	Removal from frozen environment
Diffusion	Controlled room temperature	9.8	Progressive color diffusion observed through clear window	Primary package	Removal of barrier film
Enzymatic	Controlled room temperature; cold for extended storage	8-30	Color change observed through clear window	Primary package	Breaking seal to mix liquids

An important characteristic of chemical TTIs is the precision with which the endpoint can be determined. It is difficult to quantify an indication such as a gradual color change. Accuracy may also vary widely with the control and quality of the manufacturing process. As discussed below in Validation of Temperature and Humidity Monitoring Devices, it is not possible to calibrate an individual chemical TTI because the test is, by the nature of the device, necessarily destructive. Chemical time-temperature indicators are relatively inexpensive and may be customized for a wide range of applications.

**Chemical-Physical Based TTI**— This type of TTI is based on a temperature-dependent diffusion/chemical reaction process. It consists of a pressure-sensitive tape structure, which is composed of an indicator tape and an activator tape. The indicator tape contains a dye dispersed in a polymer carrier. The activator is incorporated into an adhesive on the activator tape. Laminating the activator tape over the indicator tape causes activation. A color change or readable message occurs as the activator migrates into the indicator as a function of temperature and time. These TTIs can be manufactured to provide a wide array of time-temperature configurations. Also, because they can be made using a printing process, they can be directly integrated into a product label or provided as a stand-alone label if required.

**Chemical Polymerization Based TTI**— This type of TTI uses a polymerization process in which a color change occurs as a function of time and temperature. The color change happens when a small, colorless molecule polymerizes into a larger, colored molecule on exposure to temperatures above a specific threshold for a specified period of time. These TTIs can be applied as print process, permitting direct integration into a product label or stand-alone label. Since this type of TTI does not require activation, it must be shipped from the manufacturer on dry ice and stored at temperatures below freezing prior to use. Chemical polymerization based TTIs have somewhat limited selections of time-temperature threshold configurations.

**Diffusion Based TTI**— This type of TTI is composed of a color-dyed fat, an ester that diffuses along a porous filter paper strip or wick once the temperature exceeds the melting point of the ester. The distance the colored fat migrates is a function of the time the TTI is exposed to temperatures above the melting point of the ester. Removing a barrier film that separates the dyed fat from the wick activates these devices. They can be modified for various applications by selecting esters of different melting points, and by changing the length of the wick. These TTIs are contained within their own packaging and have limited time-temperature threshold configurations.
